Abstract

Planning, scheduling and real time optimization (RTO) are currently implemented by using different types of models, which causes discrepancies between their results. This work presents a single model of a crude distillation unit (preflash, atmospheric, and vacuum towers) suitable for all of these applications, thereby eliminating discrepancies between models used in these decision processes. Hybrid model consists of volumetric and energy balances and partial least squares model for predicting product properties. Product TBP curves are predicted from feed TBP curve, operating conditions (flows, pumparound heat duties, furnace coil outlet temperatures). Simulated plant data and model testing have been based on a rigorous distillation model, with 0.5% RMSE over a wide range of conditions. Unlike previous works, we do not assume that (i) midpoint of a product TBP curve lies on the crude distillation curve, and (ii) midpoint between the back-end and front-end of the adjacent products lies on the crude distillation curves, since these assumptions do not hold in practice. Associated properties (e.g. gravity, sulfur) are computed for each product based on its distillation curve. Model structure makes it particularly amenable for development from plant data. High model accuracy and its linearity make it suitable for optimization of production plans or schedules.
Acknowledgements

I would like to acknowledge and gratitude to my supervisor Dr. Vladimir Mahalec, for giving me this opportunity to work in this research. Without his constant support and encouragement, it is not possible to complete this research. His kindness, patience, advice, comments and suggestions were very helpful throughout the entire research.

I would like to thank my friends Pedro, Philip, Erik, Omar, Fahal, and Smriti, who helped me during this research.

I would also like to thanks all my family, especially my wife Lei and my boy Daniel, who gives me endless love and motivation.

xiv
1. Introduction

1.1 Crude distillation unit

Crude distillation units (CDUs) separate feed to a refinery into intermediate products which are further process by the downstream units or blended into the final products. CDUs are complex distillation towers, producing several products and having many degrees of freedom which can be used to fine-tune the operation. Fig.1 shows an example of a CDU in Aspen Plus (2006) consisting of a preflash tower (which remove light components from the feed), atmospheric distillation (which operates at atmospheric pressure and separates bulk of the crude into several products), and vacuum distillation (which operates under vacuum to separate heavy end of the crude into several products).

Since crude oil typically consist of large number of compounds, and its chemical compositions is not known, petroleum refining community has adopted crude characterization in a form of crude assays. An assay describes a crude oil in terms of increasing boiling point temperatures at which specific parts of the crude will evaporate; this is so called true boiling point (TBP) curve, as shown in Fig.2. The entire TBP curve is divided into non-overlapping sections (“cuts”). Other crude properties, e.g. % sulfur or gravity or viscosity, also vary from one temperature range to another temperature range (from one cut to another), as shown in Fig. 3 and Fig. 4.
Figure 1. Crude distillation unit example

Figure 2. TBP curve for crude distillation unit
Figure 3. Specific gravity of products of CDUs

Figure 4. Sulfur content of products of CDUs
If CDU is capable of perfectly sharp separation, each product stream from CDU will have
the yield corresponding to the width of the cut and its TBP curve will overlap its section
of the crude TBP curve. In reality, product distillation curves differ significantly from
their respective section of the crude TBP curve. Fig. 2 shows crude TBP and product
distillation curve for a typical atmospheric distillation tower. Back end a product TBP
curve is above the crude TBP curve and the front end of the product TBP is lower than
the crude TBP curve. One should note that the back end of the lighter cut and the front
end of the adjacent heavier cut are not equidistant from the crude TBP curve. Similarly,
midpoint of a TBP distillation curve for a cut does not lie on the crude TBP distillation
curve. Such pattern as a rule appears in practically all industrial CDUs. Unfortunately,
vast majority of the published works on simplified crude distillation modelling assume
that (i) the back end/front end points of adjacent products are equidistant from the crude
distillation curve and (ii) the midpoint of a product distillation curve lies on the crude
distillation curve.

1.2 Main contributions

This work developed a high accuracy hybrid model of a crude unit. The model does not
rely of the assumptions (i) and (ii). Hence, the model computes correctly product TBP
curves that are observed in actual CDUs. In addition, we illustrate how to represent the
crude assay data for this hybrid model and how product and crude TBP curves and property distribution curves can be used to compute bulk properties (e.g. % sulfur) of the product streams. Results computed by the hybrid model are compared with those from a rigorous tray to tray model. Differences between the predictions by the two models are within the error of the analytical instruments used to measure product distillation curves.

The main contributions for this research are:

a) Develop crude assay data modeling in a form required by the CDUs model. This model can also be used for evaluation crude assay data without commercial process simulation software such as Aspen plus, Pro/II, etc.

b) Develop hybrid model of crude distillation unit for TBP prediction. This hybrid model is not based on two widely used assumptions and almost linear except reflux ratio in atmospheric model. The small size and high accuracy of this model can be used in planning, scheduling and RTO.

c) Develop TBP based property prediction method and compare with other swing cut related methods. These property prediction methods show nearly the same prediction accuracy if using right yields which is not based on equidistance assumption. So either of property prediction methods can be integrated with hybrid TBP prediction model which can provide the yields.
1.3 Thesis overview

In section 2, the brief review of the prior work on crude distillation unit related the 
products properties prediction and application in planning, scheduling and RTO is given.

Section 3 presents a simple way to estimate pseudo-components and properties for each 
pseudo-components. The crude assay data and crude mix properties can be easily 
estimated and can be used for further model.

Section 4 describes hybrid CDUs model for TBP prediction in detail including simulation 
data generation, model developing, and verification.

Section 5 describes computation of other stream properties (e.g. specific gravity and 
sulphur). Different swing cut methods are evaluated and compared with this TBP based 
property prediction method.

Section 6 first highlights major accomplishments and result of this research, followed by 
recommendation for future research.
2. Literature review

In section is to provide a brief review of some prior work relevant to this research. Topics covered in this section include: crude distillation unit and swing cut related property prediction.

2.1 Crude distillation unit

Accurate and robust models capable of predicting CDU product yields and properties took several decades of rigorous distillation tower model developments. Rigorous model uses material and energy balance and liquid vapor equilibrium (LVE) for each tray. So it can provide tray to tray information such as internal flowrate, temperature, etc. Rigorous model is suitable for detail design and real time optimization due to these features. The first commercial flowsheet simulation software capable of solving reliably complex distillation tower models was SSI/100 by Simulation Sciences, which was released in mid 1970s. Boston et al. (1974) published “inside-out” algorithm for rigorous tray to tray simulation of distillation towers, which has become the basis for all present day algorithms for distillation of wide boiling mixtures. In mid-1980’s HYSIM introduced the use of property curves, such as % of sulfur, and their mixing via pseudo components to predict product properties other than distillation curves (Svrcek(1989)). This was soon followed by similar development in AspenPlus and Pro/II. Since early 1990s process simulation, design, and real-time optimization applications have relied on these
large scale (10,000 equations or more) nonlinear model capabilities to predict accurately
the outcome of processing crude feedstocks under specified set of operating conditions.

In addition to rigorous distillation tower models, commercial simulators usually offer a
simplified, fractionation index based models of complex distillation towers (e.g. Aspen
Plus 11.1 Unit Operation Models.(2001)). These have been provided to fill the need for
easy to configure and easy to tune models of complex distillation towers.

Rigorous distillation models available in simulation software have many equations, are
highly nonlinear and are not suitable for use in production planning and scheduling. In
order to accomplish reasonable solution times for planning and for scheduling models,
crude units have traditionally been represented by various forms of linear and recently
simplified nonlinear models of CDU behavior, as described in the next section. RTO on
the other hand uses tray to tray rigorous distillation models, which makes them too large
for use in planning and scheduling. Bagajewicz et al. (2001) used rigourous model and
heat demand-supply diagram to design conventional atmospheric crude units considering
pumparound and heat exchange network design.

Production planning and production scheduling models require multiple representations
of the same crude unit, either because there are many periods and each period has at least
one crude unit, or because the crude unit is represented by several modes of operation.
Two simplifying assumptions which as a rule are used in these simplified models are: (i) equidistance between the back end of the lighter cut and the front end of the heavier cut, and (ii) the midpoint of a product TBP curve lies on the crude TBP curve (Watkins (1979)). However, if one examines product distillation curves from actual crude distillation towers (or from rigorous tray to tray simulations), it becomes apparent that both of these assumptions are incorrect and that they introduce significant errors in predictions by the models which rely on them.

In simplified distillation unit models, FUG (Fenske-Underwood-Gilliland) mode is the best-known one. The Fenske equation estimates the minimum number of theoretical stages at total reflux (Fenske (1932)). The Underwood equation estimates minimum reflux for an infinite number of theoretical stages (Underwood (1948)). The Gilliland equation estimates the number of theoretical trays required for a given split with the reflux at a fixed multiplier of the minimum reflux ratio (Gilliland (1940)). Suphanit (1999) developed simplified model for crude distillation include modified FUG model, sider – strippers and side-rectifiers. Gadalla (2006) extended this method using in retrofitting for minimal cost and CO2 emissions. Chen (2008) developed an algorithm to find the light key and heavy key component in simplified CDUs model.

Simplest approach to modelling crude units in a mathematical programming planning model is to represent each cut by its yield and approximate its distillation curve by
a) Adding some “delta differences” $\Delta T_{Bi}$ (where $i$ can be e.g. 90%, 95%, 99%, 100%) to the crude distillation points at the back end of the product, and

b) Subtracting some delta differences $\Delta T_{Fi}$ (where $i$ can be e.g. 10%, 5%, 1%, 0%) from the crude distillation points at the front end of the product.

Such approximation is not realistic, since CDU unit can operate under variety of conditions, which leads to different sharpness of separation between adjacent products. In other words, deviations from the crude TBP curves are not constant. In addition, this model assumes that the middle section of the product distillation curve (including 50% midpoint) correspond to the crude distillation curve, which is practically never correct.

Frequently used improvement is to define distinct operating states (modes) that will be employed for the crude unit by Brooks et al.(1999). Each operating state is then characterized by different set of “delta differences” for each product. This approach improves somewhat prediction of the product front end and back end distillation points, but still suffers from the fact that these predefined operating modes cannot represent changes in separation which may be required to optimize product blending for a particular demand pattern. Similarly, middle section of the product TBP curve leads to erroneous computation of other properties.
Alattas and Grossman (2011) derived an approximate nonlinear crude distillation model which uses fractionation indices and proposed that the fractionation indices be tuned for different sets of operating conditions. This fraction index method first introduced by Geddes (1958) and extended applied in crude distillation unit by Gilbert (1966). This is similar to the simplified models used in the process simulators (e.g. AspenPlus) and also is similar to models used by some refining companies in their planning models. They also assumed equidistance between the back end of the lighter cut and the front end of the adjacent heavier cut. Alatas and Grossman (2011) did not publish a comparison of their model with rigorous tray to tray results.

All of the above research efforts have relied on the equidistance assumption and on the assumption that the midpoint of the product TBP curve lies on the crude TP curve. Mahalec and Sanchez (2012) presented a model of an atmospheric pipestill which does not assume equidistance between adjacent (back, front end) pairs and also does not assume that the midpoint of the product TBP curve lies on the crude TBP curve. The model was designed with real time applications in mind. Hence, they assumed that the temperature profile in the towers could be estimated from several available tray temperature measurements. This enabled accurate computation of the internal vapor and liquid flows in the tower in mass units (not mole units) and the internal reflux. Product TBP curves were then computed based on the crude TBP data, product yields,
stripping steam flows, and pumparound duties. The model was demonstrated to predict product TBP pints typically with less than 1% error (for 5% to 95% points on the distillation curve). An example application of the model led to an optimum which was verified as feasible via AspenPlus simulation and it was better that the result computed by optimization of the corresponding rigorous tray to tray model in AspenPlus.

Ochoa-Estopier et al. (2014) presented a review of various efforts to create reduced order crude distillation models. They developed a very accurate neural network based model of a crude distillation unit and compared its results to a rigorous simulation.

2.2 Swing cut method

In refinery planning model, a widely used method is to define a swing cut, i.e. amount of the front end of the heavier cut which is transferred to the back end of the adjacent light cut (or the amount of the back end of the lighter cut which is transferred to the front end of the heavier cut). Purpose of the swing cuts is to approximate product distillation curves. Swing cut is an assumed cut between the two adjacent products, most often with constant properties. The size of the cut is assumed as a fixed ratio (volume or weight based) to the total feed to the distillation tower, or as a TBP interval of specific size. If there are more than one crude present in the feed, then the swing cuts from all crudes are mixed and the resulting “mixed swing cut” is distributed among the adjacent products. Since the assumption is that the properties of each swing cut are constant for
the entire TBP range of the swing cut, this methodology cannot represent accurately the fact that the properties are distributed nonlinearly across TBP intervals.

Once product TBP curve is known, its bulk properties can be computed by the methodology which is used by rigorous simulation models (pseudo components “carry” with them other properties and are blended to compute product bulk properties), as illustrated by Menezes et al.(2013). Menezes et al divided each swing cut into “light part” and “heavy part”. Their approach still leaves open the question of how to determine the size of the cut in relationship to the separation capabilities of the distillation tower.

In order to apply the swing cut methodology one must decide on the amount of the transferred components and on their distillation properties. Zhang et al.(2001) applied swing-cut model by taking into account how fractions of the same distillation points swing between adjacent cuts. Li et al. (2005) employed weighted average of the yield changes by using the weight transfer ratio of each product cut. Guerra et al.(2011) also employed swing cut model. Recognizing the limitations of swing cut methodology, Pinto et al. (2000) and Neiro and Pinto (2004) proposed use of nonlinear models to derive delta models and swing cuts.
3. Crude assay data representation

3.1 Introduction

Crude oil typically consist of large number of compounds, and its chemical compositions is not known, so petroleum refining community has adopted crude characterization in a form of crude assays. This research use widely used pseudo-component method, in which the crude oil is cut into pseudo-components based on boiling ranges. In this thesis, the pseudo-component definition follows rules shown in Tab. 1. This method can easily generate the pseudo-components using for CDUs modeling especially for those without simulation software application.

There are two crude oils for modeling in this research. The light end hydrocarbon and properties show in Tab. 2. The assay data of crude oil 1 and crude oil 2 show in the Tab. 3 and Tab. 4.

3.2 Methodology

3.2.1 Crude oil assay data modeling

The procedures for crude oil assay data modeling (take crude oil 1 as an example):

a) Extrapolate the TBP curve for the crude assay data. It is very common lacking the analysis crude assay data of high boiling point range when generating pseudo components based on boiling point ranges (like crude oil 1). So we need to extrapolate the incomplete TBP curve to cover all the boiling point range. Sanchez et al. (2007) reviewed several different probability distribution functions to fit distillation curve of petroleum products. They concluded that the cumulative beta function with 4 parameters can give a good extrapolation. So in this thesis, the beta cumulative density function (Eq. 1) and objective function of Min-Max are used to perform extrapolation of TBP curve of crude oil. The formula for beta cumulative density function is given by Eq. 1. The parameters using in this equation are calculated by Min-Max optimization of the objective function shown in Eq. 2. The procedure for the extrapolation shown in Fig.5. The extrapolation results for crude oil 1 TBP curve are shown in Tab. 5, while the Fig. 6 compares the extrapolated curve with AspenPlus result. We can see that four parameters beta function gives us accurate extrapolation when compared with Aspen plus.
\[ f(x, \alpha, \beta, A, B) = \int_{A}^{B} \frac{1}{B-A} \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} (\frac{x'-A}{B-A})^{\alpha-1}(\frac{B-x'}{B-A})^{\beta-1}dx'. \tag{1} \]

where \( \Gamma \) is the standard gamma function. \( \alpha, \beta, A, B \) are the four parameters for the beta function. \( \alpha \) and \( \beta \) are positive parameter that control the shape of the distribution. \( A \) and \( B \) parameters set lower and upper bounds on the distribution and \( x \) is the normalize crude oil temperature. \( f \) is the beta accumulative density function.

Calculate \( LV_{\text{pred},i} \) from Eq. 1 using normalized temperature given by Eq. 3 and minimize deviations from the crude assay TBP points by using Eq. 2:

\[
\text{Min} \text{max}_{i=0}^{n}(LV_{\text{pred},i} - LV_{\text{assay},i})^2 \quad i = 0...n \text{ known crude assay data} \tag{2} \]

\[ TBP_{\text{norm}} = \frac{TBP_{\text{assay}} - TBP_{\text{min}}}{TBP_{\text{max}} - TBP_{\text{min}}} \tag{3} \]

\( TBP_{\text{norm}} \) is the normalized crude oil TBP point

\( TBP_{\text{min}} \) and \( TBP_{\text{max}} \) define the range of crude oil TBP points

b) Use linear interpolation to compute the volumetric percentage of each pseudo component. Once we define the boiling point range for each pseudo component, the volumetric percentage of each pseudo component can be calculated. Fig. 7 compares the results from this procedure with AspenPlus.
c) Use linear interpolation to compute the specific gravity of each pseudo component. The mid-point of the pseudo component TBP range is used as this pseudo component boiling point. The specific gravity can be obtained by linear interpolation of specific gravity curve of crude oil. Fig. 8 compares the results with Aspen plus.

d) Use linear interpolation to calculate the sulfur content for each pseudo component. Fig. 9 compares the results with Aspen plus.

Figure 6. TBP curve extrapolation results for crude oil 1 using beta function

Figure 7. Volumetric percentage for each pseudo component for crude oil 1
Figure 8. Specific gravity for each pseudo component for crude oil 1

Figure 9. Sulfur content for each pseudo component for crude oil 1
After getting the property distribution curve, the bulk properties can be estimated by accumulating the curve according to the type of properties (volumetric based or mass based). For volumetric based properties (such as specific gravity), Eq. 4 is used. For mass based properties (such as sulfur), Eq. 5 is used.

\[ Bulk\ Prop_{vol} = \sum_{i=0}^{n} vol_i \times Prop_i \quad i = \text{pseudo component} \]  

\[ Bulk\ Prop_{mass} = \frac{\sum_{i=0}^{n} vol_i \times SG_i \times Prop_i}{\sum_{i=0}^{n} vol_i \times SG_i} \quad i = \text{pseudo component} \]

### 3.2.3 crude mix modeling

The procedures for crude oil mix modeling:

Cumulate the volumetric for light end part and each pseudo component to generate TBP curve for crude mix. Eq. 6 is used to calculate the volumetric for each pseudo component. Then TBP curve for the crude mix is calculated by accumulating the volumetric of each pseudo components.

\[ vol_i = \sum_{j=0}^{n} vol_{i,j} \times fraction_j \]

\[ i = \text{pseudo component}; \ j = 1,2 (\text{crude oil 1, crude oil 2}), \]

\[ \text{fraction means the fraction of a specific crude oil in the crude mix} \]

Cumulate volume based properties (such as specific gravity) as Eq. 7.

\[ prop_i = \sum_{j=0}^{n} fraction_{vol,j} \times prop_{i,j} \]
\[ i = \text{pseudo component}; \quad j = 1, 2(\text{crude oil 1, crude oil 2}) \]

Cumulate weight based properties (such as sulfur) as Eq. 8.

\[ \text{prop}_i = \frac{\sum_{j=0}^{\text{mixture}} \text{fraction}_{\text{mol}, j} \cdot \text{SG}_{i, j} \cdot \text{prop}_{ij}}{\sum_{j=0}^{\text{mixture}} \text{ratio}_{\text{mol}, j} \cdot \text{SG}_{i, j}} \]  \quad (8)

\[ \text{prop}_i = \text{pseudo component}; \quad j = 1, 2(\text{crude oil 1, crude oil 2}) \]

Once property curve is obtained, the bulk properties for crude mix can be calculated using Eq. 4 and Eq.5.

3.3 Case study

3.3.1 Crude oil results

There are four different methods used to represent crude assay data. The method includes all scenarios with or without aspen plus data shown in Tab. 6. In the Tab. 6, the middle point means the middle points of each pseudo component range are used as normal boiling point for respective pseudo component. Pricewise linear interpolation is used to calculate the respective pseudo component properties such as TBP, specific gravity and sulfur. For crude oil 1, the TBP, SG, and sulfur prediction comparison shown in Tab 7-9 compared with Aspen plus results. For crude oil 2, the TBP, SG, and sulfur prediction comparison shown in table 10-12 compared with Aspen plus results.

4. Hybrid model for TBP prediction

4.1 Introduction

Sample crude distillation unit (see AspenTech “Getting Started with Petroleum Distillation Modelling” (2006)) used in this research is shown in Fig.1. It consists of a preflash tower, an atmospheric distillation tower, and of a vacuum distillation tower. Rigorous model of this unit is used in this work as a substitute for an actual crude distillation unit. “Plant data” used in this study have been generated from this rigorous model. All volumetric flows are expressed as liquids at the standard conditions; all measurements will be expressed in imperial units, as it is customary in North American refineries.

If each tower in the CDU was carrying out perfect, sharp separation, then the entire feed would be separated into cuts as shown by dashed vertical lines in Fig. 2 and each product would have TBP curve identical to the corresponding section of the crude feed. Note that Fig. 2 represents all products from the CDU. Since separation is not perfect, the actual product distillation curves are represented by S shaped curves as shown in Fig.2.

4.2 Material and energy balances

CDU distillation towers have a significant amount of stripping steam as their feeds. Since water does not mix with hydrocarbons, volumetric or mass balances for
hydrocarbons in each tower will be considered separately from the water balances.

Volumetric balances (on a dry basis) for the three distillation towers are:

Preflash tower:

\[ F_{\text{feed}_p}^{(\text{dry})} = F_{\text{igh}}^{(\text{dry})} + F_{\text{nph}}^{(\text{dry})} + F_{\text{feed}_p}^{(\text{dry})} \]  \hspace{1cm} (9)

Atmospheric pipestill:

\[ F_{\text{feed}_a}^{(\text{dry})} = F_{\text{nph}}^{(\text{dry})} + F_{\text{kero}}^{(\text{dry})} + F_{\text{di}l}^{(\text{dry})} + F_{\text{ago}}^{(\text{dry})} + F_{\text{feed}_a}^{(\text{dry})} \]  \hspace{1cm} (10)

Vacuum pipestill:

\[ F_{\text{feed}_v}^{(\text{dry})} = F_{\text{vgo}}^{(\text{dry})} + F_{\text{hydro}}^{(\text{dry})} + F_{\text{resid}}^{(\text{dry})} \]  \hspace{1cm} (11)

Water mass balances are:

Preflash tower:

\[ M F_{\text{stmp}_f} = M F_{\text{water}_f} \]  \hspace{1cm} (12)

Atmospheric pipestill:

\[ M F_{\text{stmp}_a} + M F_{\text{sskero}} + M F_{\text{ssdlit}} + M F_{\text{ssAGO}} = M F_{\text{water}_a} \]  \hspace{1cm} (13)

Vacuum pipestill:

\[ M F_{\text{stmp}_v} = M F_{\text{top-vapor}} \]  \hspace{1cm} (14)
Energy balances will also be written separately for hydrocarbons and for water.

Preflash tower:

\[ F_{\text{feed}_{pf}}(\text{dry}) \cdot \rho_{\text{feed}_{pf}} \cdot h_{\text{feed}_{pf}} + Q_{\text{duty}_{pf, fur}} = F_{\text{ig}t}(\text{dry}) \cdot \rho_{\text{ig}t} \cdot h_{\text{ig}t} + F_{\text{nph}}(\text{dry}) \cdot \rho_{\text{nph}} \cdot h_{\text{nph}} + F_{\text{feed}_{aw}}(\text{dry}) \cdot \rho_{\text{feed}_{aw}} \cdot h_{\text{feed}_{aw}} + Q_{\text{cond}(\text{dry})_{pf}} \quad (15) \]

\[ MF_{\text{stn}_{pf}} \cdot H_{\text{stn}_{pf}} = MF_{\text{water}_{pf}} \cdot h_{\text{water}_{pf}} + Q_{\text{cond}(\text{water})_{pf}} \quad (16) \]

\[ Q_{\text{cond}(\text{wet})_{pf}} = Q_{\text{cond}(\text{dry})_{pf}} + Q_{\text{cond}(\text{water})_{pf}} \quad (17) \]

Atmospheric pipestill:

\[ F_{\text{feed}_{ap}}(\text{dry}) \cdot \rho_{\text{feed}_{ap}} \cdot h_{\text{feed}_{ap}} + Q_{\text{duty}_{ap, fur}} = F_{\text{nph}}(\text{dry}) \cdot \rho_{\text{nph}} \cdot h_{\text{nph}} + F_{\text{kero}}(\text{dry}) \cdot \rho_{\text{kero}} \cdot h_{\text{kero}} + F_{\text{dsl}}(\text{dry}) \cdot \rho_{\text{dsl}} \cdot h_{\text{dsl}} + F_{\text{ago}}(\text{dry}) \cdot \rho_{\text{ago}} \cdot h_{\text{ago}} + F_{\text{vp-feed}}(\text{dry}) \cdot \rho_{\text{vp-feed}} \cdot h_{\text{vp-feed}} + \sum_{k=1}^{2} Q_{\text{duty}_{a,P, A_k}} + Q_{\text{cond}(\text{dry})} \quad (18) \]

\[ MF_{\text{stn}_{ap}} \cdot H_{\text{stn}_{ap}} + \sum_{i=1}^{3} (MF_{\text{ss}_{i}} \cdot H_{\text{ss}_{i}}) = MF_{\text{water}_{ap}} \cdot h_{\text{water}_{ap}} + Q_{\text{cond}(\text{water})_{ap}} \quad (19) \]

\[ i = 1, 2, 3(\text{kero}, \text{dsl}, \text{ago}) \]

\[ Q_{\text{cond}(\text{wet})_{ap}} = Q_{\text{cond}(\text{dry})_{ap}} + Q_{\text{cond}(\text{water})_{ap}} \quad (20) \]

Vacuum pipestill:

\[ F_{\text{feed}_{vp}}(\text{dry}) \cdot \rho_{\text{feed}_{vp}} \cdot h_{\text{feed}_{vp}} + Q_{\text{duty}_{vp, fur}} = F_{\text{LVGO}}(\text{dry}) \cdot \rho_{\text{LVGO}} \cdot h_{\text{LVGO}} + F_{\text{HVGO}}(\text{dry}) \cdot \rho_{\text{HVGO}} \cdot h_{\text{HVGO}} + F_{\text{resid}}(\text{dry}) \cdot \rho_{\text{resid}} \cdot h_{\text{resid}} + \sum_{k=1}^{2} Q_{\text{duty}_{v, P, A_k}} \quad (21) \]

\[ MF_{\text{stn}_{vp}} \cdot H_{\text{stn}_{vp}} = MF_{\text{top-vapor}} \cdot H_{\text{top-vapor}} \quad (22) \]
Steam balance for VP tower (Eq. 22) assumes that the entire vapor stream from the top of the VP tower is steam.

**4.2 Enthalpy calculation**

We need to compute unit enthalpies \([\text{energy/mass}]\) of hydrocarbon streams, energy supplied by the furnace, energy removed by the condenser, and the pumparound duties. We assume that at some base operating conditions we have available bulk thermodynamic properties (stream enthalpy, specific heat capacity, density, and heat of vaporization). Thermodynamic properties at conditions different from the base case are then computed as incremental changes from the base case. We will also assume that the pressure in each distillation tower does not vary significantly from the pressure at the base operating state, as is the case in refinery operations. Computation of energy balances is carried on a dry basis, disregarding steam balances. This does not have an impact on the accuracy of calculation, since the stripping steam flows through the tower without a large change in the steam enthalpy and it is condensed at the top of the tower.

Since the model will be used to predict operation under a variety of conditions, temperatures of the liquid streams leaving e.g. atmospheric distillation tower will vary. If we employ \([\text{energy/mass}]\) instead of \([\text{energy/mole}]\), we will notice that the specific heat capacities of hydrocarbons of similar molecular weights are approximately the same. Therefore, if the composition of a stream varies around some base composition, the
specific heat capacity of the material remains practically constant. For instance, if kerosene 95% point changes by 10 or 20 deg F, there are some changes to its composition but its specific heat capacity remains practically constant. Since rage of changes in operating conditions is relatively small with respect to the base case, we can also assume that the specific heat capacities of individual streams do not vary with temperature when the distillation tower moves from one operating state to another. Therefore, unit enthalpy of a stream can be calculated by Eqs. (15) and (16) for liquid and vapor streams, respectively.

\[ h_i = h_i^0 + C_i,L(T_i - T_i^0) \]  \hspace{1cm} (23)

\[ H_i = H_i^0 + C_i,V(T_i - T_i^0) \]  \hspace{1cm} (24)

Temperature of a stream leaving a side-stripping tower differs from the temperature of the main tower draw-off tray by some difference. This difference changes somewhat from one set of operating conditions to another, but for purposes of energy balance calculations it can be assumed to be constant. Hence, if we can estimate the temperature at the draw-off tray, then we can calculate the temperature of the stream leaving the side-stripping tower. Temperature at the draw-off tray varies with the boiling point of the material on that tray, which is also the same material as the one leaving the main tower and it is closely related to the product stream from the side-stripper. Front end of
the distillation curve of the product stream is heavier than the front end of the material on
the draw-off tray, due to additional separation and the steam used in the side-stripper.
These considerations lead us to a relationship between the draw-off tray temperature, the
product cut point temperature, and (stripping steam/product flow) ratio, Eq. (17) for each
of the side products \( i \).

\[
T_{\text{draw-off.tray},i} = a_0 + a_1 \times c_u T_{\text{ap},i} + a_2 \times s s_i / y_{\text{ap},i}
\]  

(25)

and the product \( p \) stream temperature is then:

\[
T_i = T_{\text{draw-off.tray},i} + a_3
\]  

(26)

Heat duty of the condenser for the atmospheric tower can be computed from the heat of
vaporization of the distillate and the total liquid leaving the condenser. Maxwell (1932)
presented heats of vaporization for hydrocarbons at various pressures, showing that at the
pressure of 1 atmosphere the heats of vaporizations of C7 to C10 hydrocarbons are within
5% of each other. Since naphtha composition can vary significantly from one operating
state to another, and since the condenser is a very large contributor in the energy balance,
heat of vaporization of naphtha needs to be estimated as accurately as possible.
Mid-point at the distillate TBP distillation curve T50d is a good surrogate for naphtha
composition. We can use linear approximation around the base operating conditions, as
shown by Eq. (19), to compute the heat of vaporization of the distillate. Fig. 10 shows
the relation between naphtha TBP 50% point and the latent heat for naphtha. From Fig.10, the straight line is used for regression. The $R^2$ is only 0.6965, but the error of prediction is about $\pm 5 \text{mbtu/lb}$ compared with average value $192 \text{mbtu/lb}$, the error is about 2.5%. Fig. 11 shows the comparison of the predicted value of latent heat and the latent heat value from AspenPlus with three different crudes at wide range of operation conditions. Approximated heat of vaporization has at most 2.5% error compared to the rigorous calculation from a comprehensive thermodynamic package.

$$\lambda_d = \lambda^0_d + a_d \times (TBP_{d,50} - TBP^0_{d,50})$$  \hspace{1cm} (27)

More accurate computation of the latent heat of naphtha can be accomplished by an iterative procedure by estimating naphtha TBP curve from the model, recalculating the heat of vaporization, estimating again naphtha heat of vaporization, etc. until the desired accuracy is achieved. Since the model predictions are already very accurate, such iterations are not necessary and we have verified such conclusion by experiments.
Figure 10. Relationship between naphtha TBP50 and latent heat

\[ y = 0.3398x + 95.94 \]
\[ R^2 = 0.6965 \]

Figure 11. Latent heat approximation VS latent heat computed by AspenPlus
4.3 Methodology

Distillation curves shown in Fig. 12 illustrate that the product distillation curves as a rule do not overlap with the feed distillation curve. This is the case in general, not just for the example model used in this work. Hence, we can not assume that the middle section of the product TBP curve coincides with the feed TBP and then add corrections to the front end and the back end. Such procedure leads to an erroneous product TBP curve which then leads to inaccurate prediction of other properties, since they are computed via their association with the product pseudo component distribution.

Instead of assuming that the middle section of the product TBP curve lies on the feed TBP curve, we need to estimate it from tower operating data, as introduced by Mahalec and Sanchez (2012) (Fig. 12). After that, deviations from the front and the back ends of the line are estimated, as shown in Fig. 12. The procedures for two steps method shown in Fig. 13.
Figure 12. Example of kerosene TBP curve estimation

Figure 13. Procedures for two steps method
The middle section of the curve is predicted as by partial least squares (PLS) model using feed TBP curve and the yield of individual products. This section represents how a given distillation tower separates the bulk of the crude among the products, based on the tower structure. It is not directly impacted by changes in other operating conditions, other than through their impact on the yield of individual products. The vertical deviations between the middle section straight line and the front and back sections are predicted by a different PLS model using cut information and operating conditions.

Cumulative cut width of each product \((ccwp_{a,i})\) is defined as:

\[
ccwp_{a,i} = \sum_{i=0}^{i} \frac{y_{u,i}}{feed_u}
\]  

(28)

Then the cut point temperature \((cutt_{a,i})\) of each product can be calculated from the feed TBP curve as shown in Fig. 14.
Separation in the tower is governed by the number of trays and by the internal reflux. Since in production planning and scheduling we do not know the temperature profile in the tower, the model uses external reflux to determine the separation in the tower. In order to account for the internal vapor flows in the tower, the model uses fraction of the feed that vaporizes at the furnace coil outlet temperature (COT).

### 4.4 Preflash Tower

Purpose of the preflash tower is to separate the light components from the crude. From planning or scheduling viewpoint, specifying the overhead distillate flowrate is the most
important decision. In order to increase accuracy of the predictions, the model requires the condenser temperature (which can be assumed constant for planning and scheduling applications), stripping steam flow and overflash. In addition to product properties, the model calculates furnace COT (see Tab. 16). Alternatively, for use in plant operation, one can specify COT and the model calculates the overflash, as shown in Tab. 17.

</table>

Equations to predict product TBP curve of the liquid distillate are as follows:

The straight line through the middle section:

\[ TBP_{i,j} = a_{i,j,0} + a_{i,j,1} \cdot TBP_{feed_{pf,10}} + a_{i,j,2} \cdot ccw_{pf,i} + a_{i,j,3} \cdot cutt_{pf,i} \]  \hspace{1cm} (29)

\[ i = 0(\text{nph}) \ j = 30, 50, 70 \]

\[ TBP_{i,j} = a_{i,j,0} + a_{i,j,1} \cdot TBP_{feed_{pf,30}} + a_{i,j,2} \cdot ccw_{pf,i} + a_{i,j,3} \cdot cutt_{pf,i} \]  \hspace{1cm} (30)

\[ i = 1(\text{feed}_{op}) \ j = 30, 50, 70 \]

The deviations from the straight line are defined as:
The deviations for the front and the back sections are given by:

\[ TBP_{i,j}^d = TBP_i - TBP_{i,j} \quad i = 1(\text{feed}_{ap}) \quad k = 01, 05, 10 \]  

(31)

\[ TBP_{i,j}^d = TBP_i - TBP_{i,j} \quad i = 0(nph) \quad k = 90, 95, 99 \]  

(32)

The deviations for the front and the back sections are given by:

\[
TBP_{i,j}^d = a_{i,j,0} + a_{i,j,1} \times COT_{pf} + a_{i,j,2} \times ccwp_{pf,i} + a_{i,j,3} \times cutt_{u,i} + a_{i,j,4} \times stm_{pf} \\

### 4.5 Atmospheric tower

Input and output variables for the atmospheric distillation tower are shown in Tab. 20. Note that we use ratio \( \frac{\text{reflux}}{\text{reflux} + \text{distillate}} \), i.e. \( \frac{R}{R+D} \) instead of \( \frac{\text{reflux}}{\text{distillate}} \), since it represents more closely the internal reflux in the tower.

Energy balance requires that we either specify one of the pumparound and compute \( \frac{R}{R+D} \) or specify \( \frac{R}{R+D} \) and compute the second pumparound. Various options for specifying the model are given in Tab. 21.
Data for development of the atmospheric pipestill model have been generated by simulating operation with a light crude feed and with the heavy crude feed for a range of operating variables (192 cases), as shown in Tab. 22. The feed was calculated by the rigorous simulation of the preflash tower, since this represented the feed as it would be produced in a real plant. The model was then tested (96 cases) against predictions from rigorous simulations for a mixed crude feed (between the light and the heavy crude). Results of the model testing are shown in Tab. 23. In these tests, all TBP points computed by the hybrid model in these test were less than 1% from the TBP points computed by the rigorous simulation.

Product distillation curves are computed from the following equations:

The straight line through the middle section:
The deviations from the straight line are defined as:

\[ TBP_{i,j} = a_{i,j,0} + a_{i,j,1} \cdot \rho_{\text{feed}_{p}} + a_{i,j,2} \cdot ccpp_{p,i} + a_{i,j,3} \cdot cutt_{p,i} \]  \hspace{1cm} (36) 

\[ i = 0(\text{hnp}) \quad j = 50, 70 \]

\[ TBP_{i,j} = a_{i,j,0} + a_{i,j,1} \cdot \rho_{\text{feed}_{p}} + a_{i,j,2} \cdot ccpp_{p,i} + a_{i,j,3} \cdot cutt_{p,i-1} + a_{i,j,4} \cdot ccpp_{p,i} \]  \hspace{1cm} (37) 

\[ i = 1, 2, 3(\text{kero, dsl, ago}) \quad j = 30, 50, 70 \]

where \( k \) are points on the distillation curve

The deviations from the straight line are defined as:

\[ TBP_{i,j} = TBP_{i,j}' - TBP_{i,j} \]  \hspace{1cm} (39) 

\[ i = 1, 2, 3, 4(\text{kero, dsl, ago, feed}_{p}) \quad j = 01, 05, 10 \]

\[ TBP_{i,j} = TBP_{i,j} - TBP_{i,j}' \]  \hspace{1cm} (40) 

\[ i = 0, 1, 2, 3(\text{hnp, kero, dsl, ago}) \quad j = 90, 95, 99 \]

The deviations for the front and the back sections are given by:

\[ TBP_{i,j} = a_{i,j,0} + a_{i,j,1} \cdot y_{ap,0} + a_{i,j,2} \cdot y_{ap,1} + a_{i,j,3} \cdot ssp,1/y_{ap,1} + a_{i,j,4} \cdot \Delta TG_{ap,i+1} + a_{i,j,5} \cdot \text{RefluxRatio} \]  \hspace{1cm} (41) 

\[ i = 0(\text{hnp}) \quad j = 90, 95, 99 \quad \text{or} \quad i = 1(\text{kero}) \quad j = 01, 05, 10 \]

\[ TBP_{i,j} = a_{i,j,0} + a_{i,j,1} \cdot y_{ap,i} + a_{i,j,2} \cdot y_{ap,i+1} + a_{i,j,3} \cdot ssp,i+1/y_{ap,i+1} + a_{i,j,4} \cdot \Delta TG_{ap,i+1} + a_{i,j,5} \cdot ccpp_{p,i} + a_{i,j,6} \cdot \varphi \]  \hspace{1cm} (42)

\[ i = 1, 2, 3(\text{kero, dsl, AGO}) \quad j = 90, 95, 99 \]

\[
TBP_{i,j}^d = a_{i,j,0} + a_{i,j,1} \cdot y_{\text{ap},i-1} + a_{i,j,2} \cdot y_{\text{ap},i} + a_{i,j,3} \cdot s_{\text{ap},i}/y_{\text{ap},i} + a_{i,j,4} \cdot \Delta TG_{\text{ap},i-1,i} + a_{i,j,5} \cdot ccw_{\text{ap},i-1} + a_{i,j,6} \cdot \varphi
\]

\[ i = 2, 3, 4(\text{dsl, AGO, feed}_{\text{op}}) \quad j = 01, 05, 10 \]

\[
TBP_{i,j}^d = a_{i,j,0} + a_{i,j,1} \cdot ccw_{\text{ap},3} + a_{i,j,2} \cdot cut_{\text{op},3} + a_{i,j,3} \cdot \varphi
\]

\[ i = 4(\text{feed}_{\text{op}}) \quad j = 90, 95, 99 \]

### 4.6 Vacuum tower

Vacuum pipestill is much simpler that the atmospheric tower. Hence it has a much smaller number of input and output variables, as shown in Tab. 24. There are two possible sets of specifications as presented in Tab. 25. Data for model development have been developed by 276 simulations (light crude, heavy crude, various operating conditions in the atmospheric tower, and the vacuum tower). Tab. 26 summarizes the range of operating conditions used for data generation. The model was tested with 147 additional sets of data for medium mix of crudes in the feed and various operating conditions. Shown in Tab.27 are the test results for the models. Similarly to the atmospheric and preflash tower models, the vacuum tower model predicts TBP points within 1% of the rigorous simulation.

### 4.9 Case studies

Test results presented in this part were for individual distillation towers, e.g. atmospheric pipestill was tested by using the crude feed computed by AspenPlus. In this part we present results of testing the hybrid model of the entire CDU unit, i.e. atmospheric tower.
feed is computed by the hybrid model of the preflash tower, and the bottoms product of the hybrid model of the atmospheric tower is the feed to the vacuum tower.

There are totally 4 tests in this section. The detail of each test is as following:

- Test #1: The purpose of this test is to evaluate the TBP properties prediction for different crudes (Heavy, medium and light crude, see Tab. 28). The operating conditions for each crude are getting from AspenPlus under same specifications (see Tab. 29). Then enter these operating conditions into this hybrid CDU unit to generate results for comparison. The compared results are shown in Tab. 30.

- Test #2a: The purpose of this test is to evaluate the TBP properties prediction for different product strategies for the light crude. Different specifications based on different production strategies were set up in AspenPlus (see Tab.31). After that
the flows computed by rigorous tray to tray model in AspenPlus were used in the hybrid model and the product TBP curves were computed from the hybrid model. The comparison of the results is shown in Tab. 32. Most of the product TBP are less that 1% away from the rigorous model prediction. An exception if 95% point for Heavy Naphtha, which has an error of 1.3%.

• Test #2b: The purpose of this test is to evaluate how accurately the hybrid model predicts the product flows. Product specifications from Tab.31 were used in both hybrid model and rigorous tray to tray model in Aspen Plus. Then the flows from the hybrid model were compared to the flows from AspenPlus model as presented in Tab. 33. Flow of heavy naphtha is up to 3% different from AspenPlus. Flow of kerosene is has 2.4% error for the max diesel operation. All other flows have errors less than 1%

• Test #3: The purpose of this test is to examine AP tower hybrid model performance in an optimization application. The objective function is described by Eq.48. Constraints are presented in Tab.34. We used specification set 4 described in section 4. The optimization problem was solved by using GRG nonlinear solver in excel and AspenPlus model was solve in equation oriented mode by DMO. In order to verify hybrid model for TBP prediction, the hybrid model product flows were entered into AspenPlus. The results are shown in Tab.35. It can be seen that the optimum computed by the hybrid model leads to the operating point which is within the specified constrains The main difference between the two models is that the hybrid model recognizes that maximization of pumparound heat duties is advantageous and increases them to the maximum allowed. AspenPlus model
stopped at a significantly lower pumparound duty which results in the objective function being approx. $3.8k per day lower.

$$Z = \max (24 * y_{ap,0} + 23.42 * y_{ap,1} + 23.1 * y_{ap,2} + 22.5 * y_{ap,3} - 0.84 * s_{ap} - 0.60 * s_{ap,1} - 0.60 * s_{ap,2} - 0.60 * s_{ap,3} - 53.95 * Q_{duty_{ap,fur}})$$ (48)

\(y_{ap,i}\) means yield of product \(i\) in atmospheric tower;
\(s_{ap}\) means bottom steam for atmospheric tower;
\(s_{ap,i}\) means stripper steam for product \(i\) in atmospheric tower;
\(Q_{duty_{ap,fur}}\) means furnace duty in atmospheric tower
\(i = 0, 1, 2, 3(\text{naphtha, kerosene, diesel, AGO})

- Test #4: The purpose of this test is to generate optimization results using different initial values for AspenPlus optimization. In this test, different initial values were used as initial points in AspenPlus using DMO (SQP algorithm). These initial values were from different production strategies and hybrid model optimization results shown in Tab. 36. Different initial values generated different optimization results shown in Tab. 37. From the table, we also can see that the optimal result is best when the optimal results from hybrid model were set up as initial values. However, the
result is slightly different with hybrid model, that’s because some of the quality constraints were slightly violated if importing hybrid model results in AspenPlus and AspenPlus generated results obeyed to all constraints. For example, heavy naphtha TBP95, the hybrid model calculation is 380 F but the value from the rigorous model is 383 F (having exactly the same values of operating variables in hybrid model and in AspenPlus). The optimization process changes the operating conditions to satisfy constraint which is no more than 380 F by reducing the flow rate of heavy naphtha. So the profit was slightly smaller than hybrid model result ($654=1,096,022-1,095,368). Different initial points were also given to hybrid model. Hybrid model always generated the same results using GRG in Excel 2010 shown in Tab. 37.

5. Product properties prediction based on TBP curve

5.1 Introduction

From the properties curve, we can find that the curve is ‘S’ sharp which is similar to the TBP curve of products. That’s because distillation is a physical process, which is only change the distribution of pseudo-components in products. The properties for each pseudo-component do not change through CDUs. The product TBP provide the information of distribution of each pseudo-component in each product. Once we get the TBP curve for a products, we can use this TBP information to predict the other properties (such as specific gravity or sulfur) using linear interpolation, so linear interpolation strategy based on products TBP curve can be used to predict products properties. For product properties, there are three types of properties, volumetric based like specific gravity, mass based like sulfur content, and index based like pour point index. In this thesis, volumetric based and mass based (specific gravity and sulfur content) will be discussed.

The swing cut method is widely used in refinery planning. Swing cut means some boiling point range for a feed can be merged into light product or adjacent heavy product. Fig.15 shows the definition of the swing cuts for atmospheric tower. From the figure, we can find that swing cut of naphtha and kerosene is located between naphtha and kerosene. When making production plan, the swing cut can be merged into naphtha or kerosene...
which depends the objective function. For example, the swing cut between naphtha and kerosene is considered as naphtha if the price of naphtha is higher than kerosene. In this way, more profit will be earned. When talking about swing cuts, two important things needed to be considered. One is the size of swing cut; the other is property of swing cut. Three different swing cut methods are used for comparison with TBP based property prediction method. They are fix swing cut method, WTR/VTR swing cut method, and Light and Heavy swing cut method. Here a brief explanation of these three swing cut methods is given.

a) Fixed swing cut method. This method is widely used in planning models. The swing cut size and properties are fixed for this method. According to Zhang(2001), the typical size of the swing cut is 5%, 7% and 9% respectively for swing cut between naphtha and kerosene, kerosene and diesel, and diesel and AGO. The properties of a swing cut can be estimated using the middle point of this swing cut in the piecewise linear interpolation of the properties curve of atmospheric tower feed (shown as asterisk points in Fig. 15).
b) Volume transfer ratio/weight transfer ratio (VTR/WTR) method. This method is used for calculating the swing cut size, and the properties of products using empirical correlation of properties curve of atmospheric tower feed. As long as known discrete production strategies (max naphtha, max kerosene, max diesel) are used in CDU operation, we can calculate the swing cut for each product. Take heavy naphtha as an example, the range of naphtha is 8.7% (for max naphtha mode of operation) to 5.9% (for max kerosene mode of operation), then the range of swing cut between naphtha and kerosene is from (5.9% to 8.7%). So the swing cut size is 2.8% (8.7%-5.9%). The hydrocarbons in this range can be become a part of either naphtha or kerosene. Then after getting the yield of each product, the property of each product can be estimated using middle point of each product.
Take heavy naphtha as an example, the middle point of 4% is used for properties calculation if the yield of heavy naphtha is 8% shown as asterisk point in Fig.16.

Figure 16. VTR/WTR method

c) Light and heavy swing cut method. The swing cut size is used as in the fixed swing cut method, and the properties calculation of the swing cut is divided into two parts, called light and heavy part. For each of these two parts, the properties can be estimated using middle point of that part piecewise linear interpolation of the properties curve of atmospheric tower feed. In Fig.17, the swing cut between heavy naphtha and kerosene is 5% (from 6% to 11%). The yield of heavy naphtha is 9%, which includes 6% (fixed part) plus 3% (from swing cut). Then the swing cut was divided into two part, the front 3% and the back 2%. In order to calculate
the properties of heavy naphtha, 3% (middle of 6% fix naphtha yield) and 7.5% [6% (fix part) plus middle point of 3% within swing cut] were used.

5.2 Methodology

There are four steps for production properties:

a) Calculate the product volumetric based properties curve (specific gravity and sulfur) by linear interpolation each TBP point of this product on mix crude specific gravity curve as Eq. 49. Piecewise linear interpolation is used to calculate specific gravity for each product. Because only discrete point on the properties curve of mix crude(TBP01,05,10,30,50,70,90,95,99), so we simply assume the
section between each discrete point is linear and use one straight line to represent it.

\[ SG_{i,j} = \text{Piecewise linear interpolation}(TBP_{i,j}, SG_{\text{mixture}}) \]  \hfill (49)

\( i = \text{product, } j = 1\%, 5\%, 10\%, 30\%, 50\%, 70\%, 90\%, 95\%, 99\% \)

\( SG_{i,j} \) means specific gravity for product \( i \) at TBP \( j \) point

\( TBP_{i,j} \) means product \( i \) at TBP \( j \) point

\( SG_{\text{mixture}} \) means specific gravity curve for mixcrude

b) Calculate the product mass based properties curve (sulfur) by linear interpolation each TBP point of this product on mix crude sulfur gravity curve as Eq.50.

Piecewise linear interpolation is used to calculate properties. Because only discrete point on the properties curve of mix crude (TBP 01, 05, 10, 30, 50, 70, 90, 95, 99), so we simply assume the section between each discrete point is linear and use one straight line to represent it.

\[ \text{Sulfur}_{i,j} = \text{Piecewise linear interpolate}(TBP_{i,j}, \text{Sulfur}_{\text{mixture}}) \]  \hfill (50)

\( i = \text{products(naphtha, kerosene, diesel, AGO)} \)

\( j = 1\%, 5\%, 10\%, 30\%, 50\%, 70\%, 90\%, 95\%, 99\% \) on TBP curve

\( SG_{i,j} \) means sulfur content for product \( i \) at TBP \( j \) point

\( TBP_{i,j} \) means product \( i \) at TBP \( j \) point

\( SG_{\text{mixture}} \) means sulfur content curve for mixcrude

c) Calculate the bulk volumetric property of the product by accumulation that properties curve by volume as Eq. 51. For property prediction, only fractions from TBP 1% to 99% are used, so denominator is \( 98(98 = 99 - 1) \).
d) Calculate the bulk mass property of the product by accumulation that properties curve by weight as Eq. 52. For property prediction, only fractions from TBP 1% to 99% are used, so denominator is 98 ($98 = 99 - 1$).

\[
SG_i = \sum_{j=1}^{98} \frac{((SG_{i,j+1} + SG_{i,j}) \times (LV_{j+1} - LV_j))/2}{SG_i} 
\]

\[i = \text{products(naphtha, kerosene, diesel, AGO)}\]
\[j = 1\%, 5\%, 10\%, 30\%, 50\%, 70\%, 90\%, 95\%, 99\%\]

\[
SG_{i,j} \text{ mean specific gravity for product } i \text{ on TBP } j \text{ point}
\]

\[
Sulfur_i = \sum_{j=1}^{98} \frac{(SG_{i,j+1} + SG_{i,j}) \times (LV_{j+1} - LV_j)/2 + (Sulfur_{i,j+1} - Sulfur_{i,j})/2}{SG_i \times 98}
\]

\[i = \text{products(naphtha, kerosene, diesel, AGO)}\]
\[j = 1\%, 5\%, 10\%, 30\%, 50\%, 70\%, 90\%, 95\%, 99\%\]

\[
Sulfur_{i,j} \text{ mean specific gravity for product } i \text{ on TBP } j \text{ point}
\]
5.3 Case study

Crude unit model describe in AspenPlus (2006) manual on petroleum process modelling is used in these case studies. TBP based property prediction method which uses the hybrid model results is compared with fixed swing cut method, weight transfer ratio method, light/heavy swing cut, and with the rigours results generated by AspenPlus.

Three sets of test have been carried out for four different modes of operation (standard operation, maximum naphtha, maximum kerosene, and maximum diesel). The results are presented in English system of units, since they are prevalent in refinery operations in North America.

- **Test #1: verification of hybrid model prediction accuracy for TBP curves.**

TBP 5% point and TBP 95% points of each products were specified in AspenPlus tray to tray model to obtain the volumetric flowrate of each product. Details of the specifications are shown in Tab.38, which is different with only the TBP 99% specification for each products in AspenPlus by Li et al. (2005). The initial boiling points (IBPs), final boiling points (FBPs), and the flowrates were calculated by AspenPlus (Tab.39 and Tab.40 respectively). These product flowrates, stripping steam flows, pumparound duties and reflux/(reflux + distillate)] were inputs to the hybrid model which computed its own predictions of the product TBP curves. Tab.41 compares the results from the hybrid
model with the rigorous AspenPlus model. TBP points computed by the hybrid model are less than 0.5% different from the results of AspenPlus rigorous CDU model. The only exception is the LV% point for naphtha.

- **Test #2: Evaluation of error introduced by equidistance assumption**

Previously published simplified CDU models rely on the assumption that the crude TBP is in the middle of the distance between FBP and IBP of the TBP curves of the adjacent products. Four different modes of operation (standard, max naphtha, max kerosene, and
max diesel) are used to test this assumption. Results from the rigorous model (Tab.42) were used to calculate the midpoint of adjacent products. For instance, under standard operation kerosene 99% TBP point is 550.0, while diesel 1% TBP is 406.0. The middle point between them is 478.0 as shown in Tab. 42. Equidistance assumption means that the cutpoint between kerosene and diesel corresponds to the 478 F point on the crude TBP curve, which is 24.6 LV% as shown in Tab. 43. Rigorous CDU simulation shows that the cutpoint between kerosene and diesel is actually at 28.3 LV%, i.e. the error is 3.7% of the crude volume which correspond to 17% error in the kerosene yield. Complete comparison for all four modes of operation is presented in Tab.43. It can be seen that errors in product yields are significant for kerosene, diesel, and AGO shown in Fig. 18.

Figure 18. Yield result compared equidistance with AspenPlus
Test #3: Evaluation of methods to compute product bulk properties

There are four test cases in this test as shown in Tab. 44. The typical size of the swing cut as introduced by Zhang (2001) is used in this thesis. Swing cut between naphtha and kerosene is 5%, between kerosene and diesel is 7%, and between diesel and AGO is 9%. In this case study, volumetric transfer ratio (VTR) is used because the volumetric flowrates are used. In case 1 ("fixed cut"), the size and the properties of swing cut are fixed. In case 2 ("VTR"), the size of swing cut is calculated by VTR. The properties are determined by high order polynomial correlations. In case 3 ("L/H cut"), VTR is used due to volumetric flowrate. In case 3, the size of the swing cut is fixed, but the properties of this swing cut are separated into light and heavy part. The properties of light and heavy part are calculated as a linear relationship between the properties at their adjacent hypothetical interfaces.

For "fixed cut" and "L/H cut" methods properties are computed by blending the swing cut properties with the bulk of the corresponding product. In case 4 (this work, "TBP"), the size of the swing cut does not need to be specified; properties are calculated as described above.

Tab. 45 shows yield, specific gravity, and % sulphur for the middle section and the cuts corresponding to each product. These data were used to compute product properties.
shown in Tab.46 and Tab.47 (specific gravity and % sulphur, respectively). Also shown in these tables are the results from the rigorous model in AspenPlus and from the TBP method described in this thesis. For data used in this work, for monotonically increasing property (e.g. specific gravity), error relative to AspenPlus is approximately the same for all for cases (four methods of computing cuts and product properties), see Tab. 46. Properties which do not increase monotonically with (LV%, TBP) points (e.g. sulphur) are predicted much more accurately by using TBP method combined with the accurate TBP predictions from the hybrid model, as illustrated by Tab. 47. Distribution specific gravity is shown in Fig.19, while sulphur distribution is shown in Fig. 20.

Figure 19. Specific gravity of products using yield based on equidistance assumption

Figure 20. Sulfur content of products using yield based on equidistance assumption

- Test #4: What is the major source of error for swing cut methods?
Since there is a fairly large error in computing product yields via swing cut methods, this test is to evaluate its impact on the accuracy of the product properties predictions. There are 6 TBP constraints, we just have 4 manipulate variables. So I try to find the solutions which give TBP as close as possible. The TBP constraint results shown in Tab. 48 and the flowrate compared with AspenPlus shown in Tab. 49. Instead of using product cumulative cuts (cumulative yields) from the swing cut methods, we substituted the yields from the hybrid model and from them calculated the corresponding (swing) cuts, as shown in Tab. 50. In order to compared with previous results, I fix the stripper steam the same as AspenPlus. Then TBP constraints were specified and the yields were manipulated variables. There is not enough freedom to generate the yields exactly the same as AspenPlus.

For instance, for VTR method, the yield of kerosene changed from 17.0% to 21.5%. This eliminates the error in the cumulative cuts and makes it possible that the property calculation methods use the crude property data from the correct region of the crude assay.

From the Fig. 18, the yield of diesel is 13.5% calculated by AspenPlus shown in Tab. 43. In contrast, the yield of diesel is 10.7% computed by VTR method based on equidistance assumption shown in Tab. 43.
Specific gravity results are shown in Tab. 51 and Fig. 21. There is an improvement in accuracy, even though the prediction errors in the original swing cut methods (Tab. 46) are already around 1%. Sulphur results show much more improvement (Tab. 52 and Fig. 22), but the swing cut methods (if they are provided with the correct yields) are still not as accurate as TBP based method.

6. Conclusions

This work addresses the issue of inconsistency of predictions between the models which are used for planning, for scheduling, and for real time optimization of refinery operations. Over the last decade there have been many proposed versions of simplified crude distillation models. Most of these models rely on the assumption that at be boundary of the product cut the distance from the crude distillation curve to the front end of the heavier product is equal to the distance to the back end of the lighter product. In addition, many models assume that the mid-point of the product distillation curve lies on the crude distillation curve. Both of these assumptions are not correct as it can be seen from rigorous crude unit simulation or from plant data.

Hybrid model presented in this thesis removes both of these assumptions. It is a small size model of the crude unit (preflash, atmospheric, and vacuum towers) which predicts the unit behaviour with very small discrepancies (vast majority of them less than 1%) with respect to the rigorous tray to tray model. The model is linear, with exception of the reflux/(reflux+distillate) variable for the atmospheric tower. Volumetric and energy balance equations are complemented by PLS models which relate the operating variables to product distillation curves.

Extensive model testing has been carried out by comparing the model predictions with rigorous tray to tray model of the crude unit in AspenPlus. An optimization example
demonstrates that the optimum computed from the hybrid model is feasible and at least as good as the optimum computed by AspenPlus equation oriented mode.

The previous paper (Mahalec 2012) relied on the calculation of internal reflux ratios in the distillation tower. In order to calculate these ratios, one needs to know the temperatures on the corresponding trays. Such data are available in real-time operation but unavailable in production planning or scheduling. In addition, Mahalec and Sanchez modelled only the atmospheric distillation tower. The current work is wider in scope; it includes the preflash tower, the atmospheric tower, and the vacuum tower. It is a complete model of a crude distillation unit with accuracy close to the rigorous models. Moreover, this work includes properties prediction section which is not covered in the previous work by Mahalec and Sanchez (2012).

The current work presents a model which is suitable for production planning and for scheduling, in addition to RTO. Since tray temperatures for some future operation are not available in the planning or in the scheduling applications, the current model does not use internal reflux ratios. Instead, the current model uses directly the operating variables and the gap between selected TB points of the adjacent crude cuts.

Different swing cut (fixed-cut, weight/volume transfer, light/heavy) methods were compared with pseudo-cuts TBP based method which uses product TBP curves computed
via hybrid distillation model. Bulk product properties are computed by blending pseudo-cuts for each product as determined by the product TBP curves. Swing cut models use assumptions which lead to incorrect product TBP curves, resulting in lower yield accuracy. If swing cut method yields are replaced by the correct yields from hybrid model, for monotonically increasing crude properties (gravity), all four methods have the same accuracy. Non-monotonical properties (sulphur) are predicted more accurately by TBP pseudo-cuts method.

Small size of the model and excellent convergence properties make it suitable for applications in production planning, scheduling, and real-time optimization refinery applications. Therefore, this type of the hybrid models can be used to eliminate discrepancies (caused by different models) in the decisions between these business processes.

The future work will focus on integrating this hybrid model with other processing units in refinery like FCCU, Naphtha reformer etc. Then this refinery platform can be used for planning and scheduling related research.
