TITLE: Transient Stability of the Wien Bridge Oscillator

AUTHOR: Richard Prescott Skillen, B. Eng., (McMaster University)

NUMBER OF PAGES: 105

SCOPE AND CONTENTS: In many Resistance-Capacitance Oscillators the oscillation amplitude is controlled by the use of a temperature-dependent resistor incorporated in the negative feedback loop. The use of thermistors and tungsten lamps is discussed and an approximate analysis is presented for the behaviour of the tungsten lamp. The result is applied in an analysis of the familiar Wien Bridge Oscillator both for the presence of a linear circuit and a cubic nonlinearity. The linear analysis leads to a highly unstable transient response which is uncommon to most oscillators. The inclusion of the slight cubic nonlinearity, however, leads to a result which is in close agreement to the observed response.

ACKNOWLEDGEMENTS: The author wishes to express his appreciation to his supervisor, Dr. A.S. Gladwin, Chairman of the Department of Electrical Engineering for his time and assistance during the research work and preparation of the thesis. The author would also like to thank Dr. Gladwin and all his other undergraduate professors for encouragement and instruction in the field of circuit theory.

Acknowledgement is also made for the generous financial support of the thesis project by the Defence Research Board under grant No. 5501-06.

I Introduction

In recent years, resistors which exhibit nonlinear electric properties by virtue of a change in resistance with applied power, have found many new uses. One application lies in exercising control over the amplitude of a sinusoidal waveform without introducing the customary nonlinearity associated with most simple nonlinear limiters. Although many devices exhibit this property to some extent, we will primarily concern ourselves with two; the incandescent lamp, and the solid state thermistor. Although the electrical characteristics are extremely different for the two, they have in common the key to their ability to control without distortion; their associated time constant due to thermal inertia.

Although the thermal properties of the incandescent lamp had been qualitatively understood for a considerable time, Meacham(1) was probably the first to analyse and employ its dynamic characteristics to stabilize the amplitude of a Meachan Oscillator in 1938. His work aroused considerable interest at that time in the nonlinear aspects of the lamps and Glynne(2) and others(3),(4),(5),(6) followed by studying the dynamic behaviour of the lamps.

By the middle of the century, thermistors were also being analysed and employed for this control problem. Bollman and Kreer(7) were two of the first to realize the potential value of these solid state devices and to set up the differential equation for their dynamic behaviour. Patchett(8) employed a directly heated type of thermistor in a bridge circuit and showed that it had a figure of merit, which he defined as the change in output voltage for a change in
input voltage, of about fifty. Typically the figure of merit for the lamp bridge is less than unity. Thus the use of the thermistor would seem to indicate a more sensitive amplitude control for oscillator amplitude stabilization.

Theoretical work concerning the amplitude stability of harmonic oscillators had attracted considerable interest in the years prior to the thermal amplitude control. With its introduction some renewed interest was brought to bear on the subject.

Edson(9) examined the amplitude stability in a lamp stabilized oscillator by examining the changes in amplitude and phase of the modulation vector when a lightly modulated wave passed through the open loop feedback circuit. For the modulated wave to persist the open loop gain and phase shift of the input signal were required to be zero. An increase in gain would indicate instability or growth, while a decrease would indicate attenuation of the modulation. In his analysis the low frequency component is not considered and the feedback factor must be symmetrical about the centre frequency for a bandwidth of at least twice the highest modulating frequency used to insure that the output will be independent of phase modulation.

Gladwin examined the problem of amplitude stability in valve oscillators(11). For the class of oscillators known as separable oscillators he examined the stability of the system from the viewpoint of its characteristic equation(12). In his analysis the oscillator is initially oscillating in the steady state with a sinusoidal output of constant amplitude and frequency. The stability is examined by subjecting the output to a small variation by changing some parameter or introducing an input perturbation. This perturbation gives rise
to oscillations at certain complex frequencies which are characteristic of the feedback loop. If these terms are then considered to modulate the output, the oscillator output will consist of an infinite number of waves of the form:

$$v_{\text{out}} = \sum_{n=-\infty}^{\infty} x_n e^{(s+j\omega_n)t}$$

where $\omega_n$ is the unperturbed oscillator frequency and $s = \alpha + j\omega_m$ is the complex frequency of the disturbance or modulation. If the oscillating circuit has a reasonably high quality factor the above series can be approximated, with a good degree of accuracy, to terms of the fundamental component and the limits of the series reduce to -1 to +1. We are thus left with three components of a small perturbation.

These components can be introduced into the network equations, and give rise to three linearized equations which when solved in a matrix analysis yield the matrix determinant equal to zero. This matrix determinant is referred to as the characteristic equation of the system's stability.

For stable oscillation all of the roots of the characteristic equation must have negative real parts to insure that the amplitude of any transient will decrease with time. Although the characteristic equation cannot always be factored for complex systems, the stability can be determined by the Routh-Hurwitz criterion for certain steady state conditions.

For oscillators where the feedback factor is symmetrical about the oscillator centre frequency for a range greater than twice the highest modulating frequency, the characteristic equation can be factored to yield independent criteria for the amplitude and frequency stability.

The Wien Bridge Oscillator with a thermal amplitude compensator
can exhibit a very poor transient response during tuning or switching of the oscillator frequency control. Several investigations have been aimed at predicting its peculiar oscillatory transient response. Cooper(10) analysed a lamp stabilized Wien Bridge type of oscillator assuming a linear operational amplifier and a simple time constant for the lamp bridge circuit. The result was applied to an amplitude modulated waveform and the value of the natural modulation frequency was obtained which was in close agreement with his experimental data. The analysis did not however, predict the amplitude of the transient modulation or the time constant to any satisfactory degree. Oliver(14) pointed out that a slight nonlinearity of the operational amplifier could explain these discrepancies in his analysis of the problem.

The Wien Bridge oscillator was thus analysed for both a linear amplifier and an amplifier containing a small amount of cubic nonlinearity using the general approach of Gladwin(12) (13). The findings are compared with experimental results to check the approximations made in the analysis.
II SIMPLE FEEDBACK OSCILLATORS

(1) Conditions for Oscillation

The concept of feedback plays an important role in almost every branch of engineering and physics. Although the word feedback is in common use it is surprisingly difficult to find a precise definition. In many physical systems it is extremely hard to identify a feedback loop. From a general point of view however, we can identify feedback as a closed series of cause and effect relationships. When feedback is introduced intentionally for a desired purpose, its definition becomes considerably simpler and can usually be expressed in a mathematical form.

Figure (1) shows in block diagram form the circuit for a simple feedback oscillator.

\[ v_o = (v_{in} + v_f)A \]

and \[ v_f = v_o \beta \]

from which we can write the closed loop gain \( A' \) for the system as;

\[ A' = \frac{v_o}{v_{in}} = \frac{A}{1 - A \beta} \]  

---(1)

If we consider the amplifier gain \( A \) to be real and positive, then the
feedback function $\beta$ will be real and positive at some complex frequency $s$ for the case of the oscillator. Here $v_{\text{in}}$ would be zero while $v_{\text{out}}$ is finite. For the case of a sinusoidal oscillator, equation (1) must have a pair of imaginary poles at $s = +j\omega_0$ and $s = -j\omega_0$ which means that the feedback network will contain at least two energy storage elements. If we write the feedback function as some function of the complex frequency $s = \alpha + j\omega$ we can equate the denominator of equation (1) to zero to obtain the conditions for oscillation as;

$$A\beta(s) = 1$$

For the steady state $s = j\omega$ and the above reduces to the familiar form for steady state oscillation often referred to as the Barkhausen criterion for oscillation or the characteristic equation,

$$A\beta(j\omega) = 1$$

(2)

This concept implies unity loop gain as the criterion for oscillation, however unity loop gain at a single frequency is a necessary but not a sufficient condition for self-sustained oscillation. Clearly if the $\beta$ network provides zero net phase shift at more than one frequency, the criteria for steady oscillation is further complicated.

For simple oscillators however, where equation (2) is sufficient, the complex equation will yield two independent criterion for oscillation:

$$I_m(\beta) = 0$$

(3A)

which will determine the steady state frequency of oscillation and,

$$AR_e(\beta) = 1$$

(3B)

which stipulates the necessary gain requirement for steady state oscillation to exist. Here $I_m(\beta)$ and $R_e(\beta)$ stand for the imaginary
part of $\beta$ and real part of $\beta$ respectively.

(2) **Selectivity**

Any practical oscillator will need a value for the amplifier gain somewhat larger than that predicted by equation (3B). Consequently its output will increase until the amplifier limits the output resulting in distortion of the steady state output. Each of the harmonics present at the amplifier output will be affected similar to additional signals injected into the feedback loop and will be reduced or enhanced by the factor;

$$F(n\omega_0) = \left| \frac{1}{1-A\beta(n\omega_0)} \right|$$  \hspace{1cm} (4)

where $\beta(n\omega_0)$ is the feedback factor evaluated at the various harmonic frequencies ($n\omega_0$); $n = 2, 3, 4, \ldots$. Equation (4) can be considered as a measure of the system's selectivity. For a properly designed oscillator the feedback should change from positive to negative in the frequency range $\omega_0$ to $2\omega_0$ ensuring that all harmonics will be small. For this condition equation (4) would be small provided $|A\beta(n\omega_0)| \ll 1$. To insure that the feedback at the frequency $n\omega_0$ is negative, the factor $A\beta(n\omega_0)$ must of course be negative.

(3) **Phase - Frequency Stability**

Oscillators are also susceptible to frequency changes caused by variation of circuit elements in other than the beta network. Since the natural frequency of oscillation is identical to the frequency of zero net phase shift around the closed loop, changes in the resistive loading or phase shift in the amplifier can alter the natural frequency from the condition of equation (3A). To ensure a constant frequency of oscillation, the beta network should thus
exhibit as rapid a change of phase with frequency about $\omega_0$ as possible. We can define a measure of phase-frequency stability for the oscillator as;

$$G = \left| \frac{\Delta \phi}{\Delta \omega / \omega_0} \right|$$

which is the change in phase $\Delta \phi$ for a relative change in frequency $\omega$ about $\omega_0$ for the beta network. Equation (5) would increase for increasing frequency stability with respect to variations in amplifier or load which would effect the overall phase shift. For the limiting case where $G \to \infty$ the natural frequency of oscillation $\omega_0$ would be entirely due to the phase-frequency characteristic of the beta network.
III BETA NETWORKS FOR R-C OSCILLATORS

(1) R-C Oscillators

At frequencies below one kilocycle per second it becomes impractical to use L-C circuits for frequency determining networks due to their large size and associated low quality factors. The large size associated with these circuits can be greatly reduced by the use of resistor capacitor networks (R-C networks) at the expense of increasing the amplifier gain and the number of parameters which must be varied to alter the oscillator frequency. There are two basic groups of R-C networks which can be employed for oscillator use, the phase shift networks, and the null type networks. Examples of each type are treated in this chapter with regard to their general merits.

(2) The "R-C Oscillator Network"

One of the simplest types of beta networks required for a feedback oscillator is shown in figure (2).

\[ \beta(s) = \frac{V_f}{V_o} = \frac{ksCR_1}{s^2C^2R_1^2 + (k+2)sCR_1 + 1} \]
which for the steady state where \( s = jw \) reduces to;

\[
\beta (jw) = \frac{k}{(k+2)} \frac{1}{1 + \frac{1}{(k+2)} \left[ \frac{\omega}{\omega_b} - \frac{\omega_b}{\omega} \right]}
\]  --(7)

where \( \omega_b = \frac{1}{\text{CR}_1} \)  --(8)

The imaginary portion of \( \beta \) will vanish for the frequency \( \omega = \omega_b \) given by equation (8) at which frequency beta reduces to,

\[
\beta (\omega_b) = \frac{k}{k+2}
\]

The necessary amplifier gain for the circuit of figure (1) would be

\[
A = \frac{(k+2)}{k}
\]

for threshold of oscillation.

The transient response of this network can also be obtained from the roots of the equation \( l - A\beta(s) \) for this oscillator.

Writing the equation for \( l - A\beta(s) = 0 \) we obtain

\[
s^2 + s\omega_b(k+2-Ak) + \omega_b^2 = 0
\]  --(9)

or

\[
(s-s_x)(s-s_y) = 0
\]

This equation has two roots \( s_x, s_y \) which for the particular case of \( k = 1 \) will describe the locus shown in figure (3).

\[
s_x, s_y = -\frac{\omega_b(3-A)}{2} \pm \frac{\omega_b}{2} \sqrt{(A-1)(A-5)}
\]
We see that as the gain $A$ increases from zero, the two roots will coalesce for $A = 1$ and then separate at $-\omega_0$ on the negative real axis as shown. When the roots reach $\pm j\omega_0$ on the imaginary axis corresponding to a gain of $A = 3$, we have the condition corresponding to the threshold of oscillation; the location of the imaginary roots giving the frequency of oscillation. In the region $1 < A < 5$ the transient response can be obtained from equation (9) and will be of the general form,

$$v(t) = Ke^{\alpha_3 t} \cos(\omega_1 t + \phi)$$  \hspace{1cm} (10)

where $\omega_0 = \sqrt{\alpha_2^2 + \omega_1^2}$ and $\phi$ is the phase shift. The two roots are located at $\pm \alpha_3 j\omega_0$. For $1 < A < 3$, $\alpha_3$ will be negative and the transient will damp out with the time constant given by equation (10). For $3 < A < 5$ the output will increase until the amplifier limits slightly making the average gain over one cycle equal to 3.

For $A > 5$ the output will no longer be oscillatory, but will approach the action of the multivibrator.

This simple beta circuit would thus seem to have a poor amplitude stability due to the dependence on $A$. The network also exhibits very poor selectivity. For example equation (4) would yield for the second harmonic where $A = 3$;
This unfortunately means that any second harmonic term present in the output would be increased in amplitude rather than reduced. This beta network would thus not seem to be very useful for oscillator use.

(3) The "Phase Shift Network"

A second simple way of achieving the required beta network for an oscillator is the familiar "phase shift network" shown below in figure (4).

![Figure (4)](image)

This circuit is a simple R-C ladder type filter with a transfer characteristic

$$\beta(s) = \frac{1}{1+\frac{6}{sCR_1} + \left(\frac{1}{sCR_1}\right)^2 + \left(\frac{1}{sCR_1}\right)^3}$$ \hspace{1cm} (11)

For the steady state $s = j\omega$ and the above reduces to;

$$\beta(j\omega) = \frac{1}{1+\frac{6}{j\omega CR_1} - \frac{5}{\omega^2 C^2 R_1^2} - \frac{1}{j\omega C^2 R_1}}$$ \hspace{1cm} (12)

The ladder network could also contain more than three sections. A simple solution for a more complex ladder network can be found by the use of Pascal's triangle\(^{(16)}\), but this increases the number of
parameters which must be changed to alter the oscillator frequency.

From equation (12) we see that the odd power terms in $\omega$ contribute to the imaginary part of $\mathcal{B}_1(\omega)$. Hence for the imaginary part to vanish

$$\frac{6}{\omega CR_1} - \frac{1}{\omega^3 C^3 R_1^2} = 0$$

or

$$\omega_0 = \frac{1}{\sqrt{6} CR_1}$$  \hspace{1cm} (13)

Solving for $\mathcal{B}_1$ at $\omega = \omega_0$ yields,

$$\mathcal{B}_1(\omega_0) = -\frac{1}{29}$$  \hspace{1cm} (14)

which defines the threshold gain for the oscillator of figure (1) to be $A = -29$. Although the amplitude is dependent on gain variations for this oscillator, the selectivity is considerably better than for the previous oscillator of section III-2. From equation (4) for second harmonic terms

$$F_1(2\omega_0) = 0.368$$

and the second harmonic terms are actually reduced in the closed loop.

We conclude that this oscillator is superior to the first, although variation of the oscillator frequency requires that three components be tracked simultaneously rather than two for the first oscillator. This factor alone probably confines its use to a fixed frequency oscillator.
(4) The Wien Bridge Network

Although the oscillator of section III–(2) seemed at first glance to be extremely poor, we can convert the circuit into a type of bridge circuit such that we can exchange loop gain for added selectivity. A common circuit; the Wien Bridge, is shown in figure (5).

![Wien Bridge Circuit Diagram](image)

Figure (5)

Here the additional arm of the bridge is composed of ordinary carbon resistors $R_2$ and $R_0$.

The transfer characteristic $\beta_2$ of the above network is simply

$$\beta_2(j\omega) = \beta(j\omega) - \frac{R_2}{R_0 + R_2}$$

where $\beta(j\omega)$ has been given by equation (7). For an oscillator employing this beta network we find for $\omega = \omega_0$, the condition for threshold of oscillation is;

$$\frac{k}{k+2} \cdot \frac{R_0}{R_0 + R_2} = \frac{1}{A}$$

For given values of the amplifier gain $A$, resistance $R_2$, and parameter $k$, equation (16) defines the unique value of $R_0$ necessary for oscillation to exist. It is obvious that the higher the degree of balance of the
bridge, the higher the gain must be for the operational amplifier.

The marked improvement of the selectivity of the bridge circuit over that of section III-(2) can be easily found as the oscillator of section III-(2) corresponds to the completely unbalanced bridge where \( A = \frac{(k+2)}{k} \). The ratio of equation (4) for each oscillator is thus,

\[
\frac{F_2(nw_0)}{F(nw_0)} = \frac{\frac{1}{A\left(\frac{k}{k+2} - \beta(\omega)\right)}}{\frac{1}{k\left(\frac{k}{k+2} - \beta(\omega)\right)}} = \frac{k+2}{kA}
\]  \( - (17) \)

where \( F_2(nw_0) \) is for the Wien Bridge Oscillator. We see from equation (17) that the selectivity will be a maximum for the Wien Bridge Oscillator for a maximum value of amplifier gain \( A \) or high degree of bridge balance.

Up to this point the value of \( k \) has been left arbitrary. In the network of figure (5) however, its choice should be made to yield the maximum amplitude and frequency selectivity for the bridge circuit. From equation (16) we see that

\[
\frac{R_o}{R_0 + R_2} = \frac{k}{k+2} \frac{1}{A}
\]  \( -(18) \)

which means that the bridge is never fully balanced for finite amplifier gain \( A \). The bridge output voltage in the steady state can be found as;

\[
v_f = v_o \left[ \frac{k/(k+2)}{1 + \frac{z}{k(k+2)}} \right] - v_o \frac{k}{A} + \frac{v_o}{A}
\]

where

\[
z = \left[ \frac{\omega}{\omega_o} - \frac{\omega_o}{\omega} \right]
\]
For frequencies close to \( \omega = \omega_0 \), \( z \ll 1 \) and the equation for the output voltage can be approximated for \( A \gg 1 \) as:

\[
\left| \frac{v_r}{v_o} \right| \approx \frac{zk}{(k+2)^2} \quad -(19)
\]

This should be a maximum for maximum frequency sensitivity. Differentiating equation (19) with respect to \( k \) and setting the result equal to zero yields

\[
z \left[ \frac{(k+2)^2 - 2(k+2)k}{(k+2)^4} \right] = 0
\]

from which we find that maximum frequency sensitivity occurs for,

\[k = 2\quad -(20)\]

This result would require that \( R \approx R \) for a very high gain amplifier and this is also the value for \( R_0 \) and \( k \) for maximum amplitude sensitivity for the bridge circuit.

(5) The "Twin T" Network

Practically any three terminal null network may be used for a frequency determining branch in a bridge type oscillator. A common type of null network which could be employed is shown in figure (6). This network is commonly referred to as the "Twin T" network.

![Figure (6)]
The transfer function for the twin T network of figure (6) can be found as:

\[ \beta_3(j\omega) = \frac{1}{1 - j \frac{2(n^2+1)}{n} \left[ \frac{1}{(\omega_0 \pm \omega)} \right]} \]

where \( \omega_0 = \frac{1}{nCR_1} \)

The network thus exhibits a reciprocal type of response to the network of section III-(2). As \( \omega \to \omega_0 \) the beta function goes towards zero and hence the name of "null network" is applicable. For use as an oscillator the network can be incorporated in a bridge circuit as shown in figure (7)

![Figure (7)](image)

The complete feedback function for the oscillator of figure (1) is then given by

\[ \beta_4(j\omega) = \frac{R_o}{R_o + R_2} - \beta_3(j\omega) \]

For the resonant frequency \( \omega = \omega_0 \) we obtain the condition for threshold oscillation as;
\[
\frac{R_0}{R_0 + R_2} - \beta_3(w_0) = \frac{1}{A}
\]

and since \( \beta_3(w_0) = 0 \) this reduces to

\[
A = \frac{R_0 + R_2}{R_0}
\]

If the network is examined with regard to selectivity, we find as for the case of the Wien Bridge that selectivity is a maximum for \( A \) approaching infinity.

(b) Phase-Frequency Characteristic of Bridge Networks

It was pointed out in Chapter II that the phase-frequency characteristic of the beta network can be used as a measure of the frequency stability of the oscillator with respect to component phase shifts, in components other than the beta network itself. The Wien Bridge Oscillator can be examined with regard to equation (5). When examined the phase shift of the beta network can be found from the approximate value for phase shift close to resonance \( \phi \),

\[
\beta_2 \approx \frac{1}{A} - j \frac{k}{(k+2)^2} \left[ \frac{w}{w_o} - \frac{w}{w} \right] \quad - (24)
\]

\[
\phi \approx \tan^{-1} \frac{kA}{(k+2)^2} \left[ \frac{w}{w_o} - \frac{w}{w} \right] \quad - (25)
\]

Equation (5) can now be found close to resonance as approximately,

\[
G = \frac{d\phi}{dw} \approx \frac{kA}{(k+2)^2} \left[ \frac{1 + \frac{w^2}{w_o^2}}{1 + \left[ \frac{kA}{(k+2)^2} \left( \frac{w}{w_o} - \frac{w}{w} \right) \right]^2} \right] \quad - (26)
\]
which at \( \omega = \omega_0 \) reduces to;

\[
G(\omega_o) \sim \frac{2kA}{(k+2)^2}
\]  

For the above to be a maximum the parameter \( k \) will have the value \( k = 2 \) which is in agreement with the section III-(4). For \( k = 2 \) the result reduces to,

\[
G(\omega_o) = \frac{A}{4}
\]  

and the effect of a high gain amplifier is seen to make the oscillator almost entirely dependent on the beta network as the frequency determining element. This oscillator would thus seem to behave suitably if some means could be found with which to maintain the amplifier gain constant.

(7) **The Nonlinear Bridge Compensator**

Any compensation which could be carried out in the oscillator circuit for changes in amplifier gain would involve the use of a network with a nonlinear voltage characteristic. Compensation can be achieved if a passive nonlinear element is included in the feedback network at a point where it will change the magnitude of the feedback without affecting the steady state frequency. This is commonly called feedback limiting. For the bridge type oscillator, the bridge balance can be controlled by the thermal characteristics of a tungsten lamp or a thermistor.

As an example of the effectiveness of this type of amplitude compensation, we can analyse the oscillator circuit shown in figure(8). For the analysis we will assume that the thermal time constant of the
lamps R is much greater than the period of the steady state frequency of oscillation.

![Figure (8)]

Here we have introduced two lamps in series represented by R for the variable resistor \( R \) shown in figure (5). In the steady state the nonlinear characteristic of the lamps R can be represented to a first approximation by the experimentally determined expression,

\[
R = 900 + 170E_L
\]  

where \( R \) will be in ohms and \( E_L \) is the R.M.S. lamp voltage in volts.

For an oscillator output of \( v_0 = 8.0 \) volts R.M.S. and an amplifier gain of \( A_1 = 400 \) we find for threshold of oscillation;

\[
\frac{R}{R+R_2} = \frac{1}{2} - \frac{1}{400} = 4.975 \times 10^{-1}
\]  

which means that the portion of the output voltage across the lamp is,

\[
E_L = 4.975 \times 10^{-1} \times 8.0 = 3.980 \text{ volts R.M.S.}
\]  

Substituting this value of \( E_L \) back into equation (29) to obtain the steady state lamp resistance yields,

\[
R = 1577 \Omega
\]
and from equation (31) we obtain,

\[ R_2 = 1591 \, \Omega \]

which will be a constant for the oscillator.

If the amplifier gain changes over a period of time due to component deterioration to some new value \( A_2 = 200 \) we can calculate the change in \( R; \Delta R \) and hence the new output condition to be respectively,

\[ R + \Delta R = 1560 \, \Omega \]

\[ v_o + \Delta v_o = 7.76 \text{ volts R.M.S.} \] \hspace{1cm} (32)

Hence we see that for a 50% change in amplifier gain, the oscillator output is only changed by 3%. This method of amplitude limiting would thus seem to be quite effective in maintaining a constant steady state output voltage. In the next chapter we will examine the dynamic behavior of several thermal devices with a view towards predicting their transient effect on the oscillator.
IV TEMPERATURE DEPENDENT RESISTORS

(1) **Incandescent Lamps**

Although considerable literature on lamps has been written concerning their use in illumination, comparatively little work has ever been published with regard to their dynamic behaviour. An extensive bibliography found in Patchett's work\(^3\) contains the majority of the early literature.

Patchett\(^3\) examined a wide variety of incandescent lamps or filaments with regard to their suitability for bridge circuits which could be used as feedback limiters. His work mentioned many of the undesirable characteristics associated with lamps when used for control elements. Intermittent bridge misbalance was claimed to be one of their greatest drawbacks. He found that lamps were extremely susceptible to vibrations which in turn caused random variations in the bridge output voltage. This effect was especially pronounced for the coiled filament type of lamp. Presence of gas in the lamp envelope was also found to alter the characteristic of the lamp, as added conduction terms alter the heat transfer equations especially at certain temperatures where the gas ionizes.

Patchett\(^3\) derived an approximate solution for the thermal response time of the vacuum lamp, but the result involved a knowledge of the physical mass of the filament which makes its use somewhat limited. The thermal response time was also developed by Glynne, but the temperature coefficient of resistance used in his formula referred to the lamp's operating temperature \(\theta_0\). This coefficient would thus vary over a range of about two to one in the normal operating region.
that he used.

(2) Lamp Dynamic Behaviour

In the steady state, the exact mechanism of the heat transfer is of little concern to us, but from experimental data it has been found that,

\[ P = K_1 \theta^a \]  \hspace{1cm} \text{----(33)}

and

\[ R = K_2 \theta^b \]  \hspace{1cm} \text{----(34)}

holds fairly well apart from a small region close to the ambient or room temperature. Here \( P \) is the power radiated in watts, \( R \) is the resistance of the lamp filament in ohms at some temperature \( \theta \) in degrees Kelvin, and \( K_1, K_2, a \) and \( b \) are constants. Strictly speaking "a" varies somewhat with temperature, but equation (33) is a good approximation for the restricted temperature range of the compensator used. For an effective lamp, of the two lamps used in series in the experimental section, typical values for "a" and "b" would be \( a = 5.3 \) and \( b = 1.2 \).

If we define \( W(t) \) as the instantaneous power supplied to the lamp and \( C_T \) as the thermal heat capacity of the filament, we can write the power balance equation for the lamp

\[ W(t) = \frac{d}{dt}(C_T \theta) + P(t) \]

\[ \approx C_T \frac{d\theta}{dt} + P(t) \]  \hspace{1cm} \text{----(35)}

Here \( C_T \) has been assumed constant over the temperature range of operation.
The first term on the R.H.S. of equation (35) will be the stored energy per second and \( P(t) \) will be the instantaneous power radiated by the filament. Combining equations (33) and (34) to eliminate temperature and substituting the result in equation (35) yields,

\[
W(t) = C_T \frac{d}{dt} \left[ \frac{R(t)}{R_2} \right]^b + K_1 \left[ \frac{R(t)}{R_2} \right]^a \tag{36}
\]

For the case of the feedback limiter, the lamp \( R \) will be in series with the fixed resistor \( R_2 \) as shown in figure (9).

![Figure (9)](image)

The power supplied to the lamp would thus be;

\[
W(t) = v^2(t) \frac{R(t)}{(R(t) + R_2)^2} \tag{37}
\]

Combining equations (36) and (37) yields upon simplification,

\[
\frac{d}{dt} \left[ \frac{R(t)}{R_2} \right]^b + K_1 K_2 \left[ \frac{R(t)}{R_2} \right]^a = \frac{R(t)}{(R(t) + R_2)^2} \frac{v^2(t)}{C_T K_2 \frac{1}{b}} \tag{38}
\]

This is the approximate nonlinear differential equation for the dynamic behaviour of the lamp bridge arm shown in figure (9) and is not of any apparent standard form. A solution could be obtained by recourse to numerical or graphical methods, but the perturbation method will yield a solution about a steady state value in an analytical
form.

Let us then consider the system of figure (9) for small changes about some specified steady state temperature $\theta_0$ and resistance $R_0$. The power supplied to the lamp has been given by equation (37) and if the steady state voltage varies as $v + \delta v$, then the temperature will vary as $\theta_0 (1+x)$ where $\delta v$ and $x$ are small time varying parameters. From equation (34) we see that,

$$R = K\theta_o^b (1+x)^b$$

$$\simeq R_0 (1+bx)$$

where

$$R_0 = K\theta_o^b$$

and $x \ll 1$

Similarly from equation (33) we obtain,

$$P = P_0 (1+ax)$$

where $P_0 = K\theta_o^a$ is the steady state radiated power by definition.

If we write the variation of the supplied power as $W_0 (1+\delta)$ then equation (37) becomes,

$$W_0 (1+\delta) = \frac{(v+\delta v)^2 R_0 (1+bx)}{(R_0 (1+bx) + R_2)^2}$$

$$\simeq W_0 \left[ 1 + \frac{2\delta v}{v} + bx - \frac{2R_0 bx}{(R_0 + R_2)} \right]$$

for $x \ll 1$

Defining $\rho = \frac{R_0 - R_2}{R_0 + R_2}$ to simplify the notation the above reduces to;

$$\delta = \frac{2\delta v}{v} - \rho x$$
From the power balance equation for small changes we find that;

\[ \frac{C_T \Theta_o}{W_o} \frac{dx}{dt} = 1 + \delta - \frac{P_o}{W_o} (1 + ax) \]  \hspace{1cm} -(43)

In the steady state the supplied power \( W_o \) is equal to the radiated power \( P_o \) and the above becomes,

\[ \frac{\Theta_o C_T}{W_o} \frac{dx}{dt} = \delta - ax \]

For the value of \( \delta \) found in equation (42) the final result is;

\[ \frac{\Theta_o C_T}{W_o} \frac{dx}{dt} + ax = 2 \frac{\delta v}{v} - \rho bx \]  \hspace{1cm} -(44)

which is a linear differential equation with a solution;

\[ x = K_0 e^{-\frac{(a + \beta \phi) W_o}{C_T \Theta_o} t} + \frac{2 \delta v}{v(a + \beta b)} \]  \hspace{1cm} -(45)

Thus the system would appear to have a simple time constant given by equation (46).

\[ \tau = \frac{C_T \Theta_o}{(a + \beta b) W_o} \]  \hspace{1cm} -(46)

For the particular case of the Wien Bridge Oscillator employing a high gain amplifier \( R_o \approx R_2 \) and thus \( \phi \approx 0 \). For this case equation (46) reduces to the simple form;

\[ \tau = \frac{C_T \Theta_o}{a W_o} \]  \hspace{1cm} -(46A)
Although "a" and $C_T$ are not strictly speaking constant, equation (46) or (46A) should yield $T$ to a good approximation for small values of the perturbation $\delta v$. The steady state temperature $\theta_s$ should also be kept well above the temperature of the lamp's surroundings.

A useful expression for variations of the lamp resistance in terms of power can be obtained by further manipulation of equations (33) and (34). If we take the logarithms of both equations and combine the two resultants to eliminate the temperature, we can obtain;

$$\log R_0 = \frac{b}{a} \log P_0 + \log K_2 - \frac{b}{a} \log K_1$$  \hspace{1cm} -(47)

which is the equation of a straight line with slope

$$m_o = \frac{b}{a}$$  \hspace{1cm} -(48)

and y intercept

$$y_o = \log K_2 - \frac{b}{a} \log K_1$$  \hspace{1cm} -(49)

The actual characteristic will of course deviate from this predicted result at low power inputs where the temperature or resistance of the filament would be dependent on room temperature. The actual characteristic would thus be $\log R$ equals a constant value for low values of applied power and then gradually experience a transition where the room temperature becomes decreasingly important until equation (47) is satisfied.

For useful power inputs in the region of operation, the slope of the characteristic should obey equation (47). For typical values of "a" and "b" for the lamps used in the experimental portion the slope will be;
\[ m = \frac{b}{a} \quad \frac{1 + 2}{5.3} = 0.23 \]

We have seen that the lamp bridge shown in figure (9) is characterized by a simple time constant \( T \). This time constant will set a lower frequency limit on the use of the bridge as a control element. If the frequency is reduced for the oscillator output we would eventually reach a point where the lamp resistance would follow the oscillator output and fluctuate at twice the frequency of the oscillator. This would produce an output which would be entirely unsuitable as a control signal.

(3) Low Frequency Response

To obtain an idea of the output from the lamp bridge at low frequencies, let us examine the circuit shown in figure (10).

\[ V(t) \]

\[ R_2 \]

\[ R_3 \]

\[ V_3 \]

\[ R \]

\[ \text{Figure (10)} \]

Let the input to the bridge be a sinusoidal voltage \( V = \sqrt{2} E \sin \omega_0 t \) where \( E \) is the R.M.S. voltage and \( \omega_0 \) is the frequency in radians per second. At low frequencies as the lamp follows the sinusoid, let the resistance vary slightly about the mean value \( R_0 \) so that

\[ R = R_0 (1 + y) \]

\[ -(50) \]

where \( y \) is assumed to be a small time varying parameter. If the bridge arms are adjusted so that \( R_2 = R_0 \) then the bridge output will be;
The instantaneous current "I" through the lamp arm of the bridge is,

\[ i = \frac{v}{R+R_o} = \frac{v}{R_o(2+y)} \]  \hspace{1cm} \text{--(52)}

and the instantaneous power supplied to the lamp is;

\[ W = \frac{v^2 R_o (1+y)}{[R_o(1+y)+R_o]^2} = \frac{v^2 R_o (1+y)}{4R_o^2 (1+y)^2} \]

\[ \simeq \frac{v^2}{4R_o} \]  \hspace{1cm} \text{--(53)}

where terms in \( y^2 \) have been neglected. Corresponding to the variation in resistance, let the temperature of the filament vary about some mean value \( \theta_0 \) such that,

\[ \theta = \theta_0 (1+x) \]  \hspace{1cm} \text{--(54)}

where \( x \) is a small time varying parameter. The actual radiated power \( P \) is in general some nonlinear function of this temperature say \( P = f(\theta) \) and this can be expressed as a few terms of a Taylor Series for small nonlinearity as,

\[ P = f(\theta_0) + \theta_0 x f'(\theta_0) + \ldots \]

\[ \simeq P_0 + \theta_0 x G_T \]  \hspace{1cm} \text{--(55)}
where \( G \) has been defined as the differential thermal conductance of the filament at a temperature \( \Theta \) is \( (G_T = f'(\Theta)) \). If we again write \( C_T \) as the thermal heat capacity of the filament, the power balance for the lamp arm of the bridge can be written as;

\[
\frac{d(C_T\Theta)}{dt} = W - P
\]  \hspace{1cm} -(56)

Noting that the steady state radiated power is \( P_0 = \frac{E^2}{4R_0} \) we can evaluate equation (56) as;

\[
C_T\Theta \frac{dx}{dt} + G_T\Theta x = -\frac{E^2}{4R_0} \cos 2\omega t \hspace{1cm} -(57)
\]

This is a simple linear differential equation with a solution;

\[
C_T\Theta x = \frac{E^2}{4R_0} \left[ \frac{\omega_T}{\omega_T^2 + \omega_0^2} \cos 2\omega_0 t + \frac{\omega_0}{\omega_0^2 + \omega_T^2} \sin 2\omega_0 t \right]
\]  \hspace{1cm} -(58)

where \( \omega_T = \frac{G_T}{C_T} \)

If we define \( \gamma \) as the temperature coefficient of resistivity for variations about a temperature \( \Theta_0 \), we can write \( \gamma = \gamma \Theta_0 \). Upon substitution in equation (52) along with the value of \( \Theta_0 x \) from equation (58) we can obtain the bridge output voltage as;

\[
v_3 = \frac{E^3 \gamma}{16\pi^2 C_T R_0} \left[ \frac{\omega_T}{4\omega_0^2 + \omega_T^2} \left\{ \sin \omega_0 t - \sin 3\omega_0 t \right\} - \frac{\omega_0}{4\omega_0^2 + \omega_T^2} \{ \cos \omega_0 t - \cos 3\omega_0 t \} \right]
\]  \hspace{1cm} -(59)

In the above form the result is somewhat cumbersome, however at
practical low frequencies $2\omega_0$ is still much larger than $\omega_T$ for the tungsten lamps of the type used. For $2\omega_0 > \omega_T$ equation (59) can be approximated further to yield:

$$v_3 \propto \frac{B^3 \omega_0^3}{2 \sqrt{2} C T R_0 \omega_0} \left\{ \cos 3\omega_0 t - \cos \omega_0 t \right\} \quad -(60)$$

This result means that at the bridge balance point where we would normally expect zero output voltage, we still have an output given by equation (60). This output consists of two components of equal amplitude and ninety degrees out of phase with the bridge input voltage. The first of these components is a third harmonic of $v(t)$ while the second is at the same frequency as $v(t)$. The components should decrease quite rapidly with frequency as is seen by equation (60). In the oscillator these components would be further reduced by the factor $\frac{1}{1 - A \beta}$ in the feedback loop. As long as the feedback loop is quite selective the unwanted output from the bridge can be tolerated for even very low frequencies, however, the lamp bridge will cease to maintain the amplitude constant.

(4) Thermistors

Thermistors are basically electronic devices which utilize the change in resistivity of a semiconductor with a change in temperature or applied voltage. The devices can be either directly heated by the current flow through the semiconductor or indirectly heated by heaters depending on the type and application. The active portion of the devices is composed of complex metallic-oxide compounds using such typical oxides as manganese, nickel, copper, and cobalt.
The important factor in their application is the region of negative temperature coefficient of resistance; the resistance decreases approximately exponentially with the inverse of the absolute temperature.

Figure (11) shows a typical characteristic curve for a directly heated bead thermistor which would be suitable for the feedback compensator of the oscillator used in the experimental section.

Bollman and Kreer(7) have developed an expression for the dynamic behaviour of the thermistor in the form of a nonlinear differential equation. Although the equation is highly nonlinear it can be shown that the device can be characterized by a simple time constant to a good approximation.

The design of the thermistor bridge arm can be shown quite easily via figure (12).
Figure (12) shows three curves, the thermistor $T_1$, the series resistor $R_T$, and the combined characteristic of the two in series. Resistor $R_T$ and thermistor $T_1$ could form one arm of a bridge circuit as shown in figure (13). Let $T_0$ be the steady state resistance of $T_1$.

![Figure (12)](image)

For a proper choice of $R_T$ and thermistor $T_1$, the steady state input voltage $v_o$ will be such that $R_T = T_0$ for the bridge balance, and corresponding to this condition the combined characteristic $(T_1 + R_T)$ should have $dv/di$ very close to zero. Under these conditions any change in the steady state voltage $v$ from $v_o$ would create a large change in current $i$ and a large change in the output voltage $v_{out}$ which would unbalance the bridge considerably. This would thus seem to be a
very sensitive source of an error voltage if used as a feedback compensator.

For use in the oscillator of section III-(7) figure (8), the thermistor \( T_1 \) would take the place of the resistor \( R_2 \) and the resistor \( R_T \) would take the place of the lamps \( R \). For additional sensitivity the lamps \( R \) could remain, replacing resistor \( R_T \), although this would further complicate the selection of the lamps \( R \) and thermistor \( T_1 \).

One additional benefit which could be obtained from the use of a thermistor for the compensator is the independence of the device with respect to vibrations and their associated bridge misbalance.
(1) **Sensitivity of Wien Bridge Circuit**

In Chapter III it was found that the optimum choice for the parameter \( k \) in figure (5) was \( k = 2 \) for maximum frequency sensitivity. For \( R_o \), a passive linear resistor, this is also the criterion for maximum amplitude sensitivity for the bridge.

When a nonlinear resistor \( R \) is substituted for the resistor \( R_o \) as in figure (14), the situation is further complicated and the parameter \( k \) will have a new optimum value for maximum bridge amplitude sensitivity.

If the voltage input to the bridge is given in the steady state by,

\[
v_o = E_1 \cos \omega t
\]

and the mean value of \( R \) is \( R_o \) at some mean temperature \( \theta_o \), we can examine the effect of small voltage amplitude changes on the bridge balance. Let the input to the bridge vary in amplitude as \((E_1 + \delta E_1) \cos \omega t\) and the temperature of the lamp's filament vary as \((\theta_o + \delta \theta)\). If \( \delta \) is defined as the temperature coefficient of resistivity for the filament,
then the lamp resistance will vary as \( R_0 (1 + \delta \theta) \).

The power radiated \( P \) can be found from equation (55) as,

\[ P = P_0 + \delta \theta G_T \]  \( - (62) \)

where \( G_T \) is again the differential thermal conductance and \( P_0 \) is the steady state radiated power.

The power supplied to the lamp \( W \) is,

\[ W = \frac{R_0 (1 + \delta \theta) (E_1 + \delta E_1)}{2 (R_2 + R_0 (1 + \delta \theta))} \]  \( - (63) \)

which for small perturbations \( \delta E_1 \) where \( |\delta E_1| \ll 1 \) and \( |\delta \theta| \ll 1 \) reduces to;

\[ W \approx W_0 \left[ 1 + \frac{2 \delta E_1}{E_1} + \delta \theta (1 - \frac{2R_0}{R_0 + R_2}) \right] \]  \( - (64) \)

where \( W_0 = \frac{E_1 R_2}{(R_0 + R_2)^2} \) is the steady state power supplied and hence radiated, ie \((P_0 = W_0)\)

On the average the power supplied and radiated must be equal. Thus we can equate equations (64) and (62) to obtain;

\[ \left[ 1 + \frac{2 \delta E_1}{E_1} + \delta \theta (1 - \frac{2R_0}{R_0 + R_2}) \right] = 1 + \frac{\delta \theta G_T}{P_0} \]  \( - (65) \)

If we recall the constant \( m_o \) from section IV-(2) we can obtain

\[ m_o = \frac{\log R}{\log P} = \frac{\delta R}{\delta P} = \frac{R_0 \delta \theta}{\delta \theta G_T} = \frac{\delta \theta G_T}{P_0} = \frac{\gamma P_0}{G_T} \]  \( - (66) \)
and note from equation (16) that for an oscillator employing a high gain amplifier,

\[
\frac{R_0}{R_0 + R_2} \sim \frac{k}{k+2}
\]

then we can reduce equation (65) to;

\[
\frac{2\delta E_1}{E_1} \sim \gamma \delta \theta \left[ \frac{1}{m_0} - (1 - \frac{2k}{k+2}) \right] \tag{67}
\]

The output voltage \(v_f\) of figure (14) can thus be written and approximated as;

\[
v_f = (E_1 + \delta E_1) \cos \omega t \left[ \frac{k}{k+2} - \frac{R_o (1 + \gamma \delta \theta)}{R_0 (1 + \gamma \delta \theta) + R_2} \right]
\]

and

\[
\delta v_f \simeq -2\delta E_1 \frac{2k}{(k+2)^2} \frac{1}{\left[ \frac{1}{m_0} - 1 + \frac{2k}{(k+2)} \right]} \tag{68}
\]

For maximum amplitude sensitivity \(\left| \frac{\delta v_f}{\delta E_1} \right|\) should yield a maximum. For this condition for real values of \(k\) we find

\[
k = 2^{\frac{1-m_0}{1+m_0}} \tag{69}
\]

We note that the value of \(k\) for maximum sensitivity has been altered by the factor \(\sqrt{\frac{1-m_0}{1+m_0}}\) from the case of the linear resistor. Since we have seen that the expected value of \(m_0\) is small for the tungsten lamp, a value of \(k = 2\) will not greatly alter the amplitude sensitivity and yet it will allow the oscillator to be designed for maximum frequency sensitivity.
(2) Oscillator Stability

Stability for the oscillator is extremely important as the oscillator output should not experience any violent changes for finite changes in the circuit. We say that a linear circuit is stable when all transients decay in a finite time leaving a predominant steady state. It is thus essential to study a system's transient response when investigating the system stability.

For an oscillator, we must know the transient response to small perturbations about each of the possible "steady states". The "steady state" is where the output is a wave of constant amplitude and frequency. The equilibrium point or steady state point is then investigated by perturbing the system and examining the resultant transient. If the particular steady state is stable, the transient disturbance must decrease with time, and if unstable the transient will be enhanced. In some systems a large perturbation can cause a change in the steady state while a small perturbation will not. The time constant with which a disturbance decreases may also be of sufficient duration to be annoying. For these reasons some qualification must be imposed on the meaning of stability for a system depending on its application.

If we perturb an oscillator which is initially oscillating with a sinusoidal output, the perturbations will give rise to a modulation of the output at some complex frequency \( s = \alpha + j\omega_m \) which can be obtained by solving the network equations for the perturbation. The transient response can then be evaluated with regard to stability.
In this section we will examine the transient response of the Wien Bridge Oscillator for small perturbations of the lamp resistance $R$ for the circuit shown in figure (15).

The amplifier $A$ is assumed to be linear with gain $A_0$. The lamp $R$ is perturbed by introducing or removing the resistor $\epsilon R_0$ via the switch $S_w$.

During the steady state oscillation the switch $S_w$ is closed and the output voltage $v_o$ will be given by:

$$v_o = E_1 \cos(\omega_0 t + \phi)$$  \hspace{1cm} (70)$$

where $\omega_0 = 1/CR_1$ is the steady state frequency. For oscillator frequencies above the lower frequency limit of the lamp bridge, the output amplitude and frequency are constant in the steady state and the lamp resistance will be a steady state value $R_0$. If the amplifier has a high gain such that $A \gg 1$, the resistor $R_2$ will also have the approximate value $R_2 \approx R_0$.

If the resistance $\epsilon R_0$ is introduced into the circuit at time $t=0$ via the switch $S_w$, the output must change correspondingly by a time varying parameter $\delta v_o$ such that.
\[ v_0 + \delta v_0 = (E_1 + \delta E_1)\cos(\omega_0 t + \phi) \]  

---(71)

The change in the output voltage will be a function of the amplitude only as shown in equation (71) if the response characteristic of the feedback network is symmetrical about the oscillation frequency. For any other condition the changes in amplitude would be accompanied by changes in the oscillation frequency. We are justified in making this approximation here at least for small perturbations.

Equation (71) can be written in the exponential form using the exponential identity for the cosine term to yield,

\[ \delta v_o = \frac{E_1 d}{\pi} \left[ e^{(s+j\omega_0)t+j\phi} + e^{(s-j\omega_0)t-j\phi} \right] \]  

---(72)

where the relative change in \( E_1 \) has been written as

\[ \frac{\delta E_1}{E_1} = d e^{st} \]  

---(73)

where \( S = \alpha + j\omega_m \) is the complex frequency of the modulation.

The change in the output is seen from equation (72) to be composed of two terms at the complex frequencies \( S \pm j\omega_0 \).

In the steady state the output \( v_1 \) from the frequency selective arm of the bridge of the circuit, Figure (15) was,

\[ v_1 = \frac{v_0}{2 + \frac{j \omega}{\omega - \omega_0}} \]  

---(74)

The change in \( v_1 \) for the change in \( v_0 \) will thus be

\[ \delta v_1 = \delta v_0 \frac{1}{2 + \frac{j \omega}{\omega - \omega_0}} \]
for each of the two complex frequencies of the output $\delta v_o$ given in equation (72). The output from the frequency selective arm $\delta v_1$ is thus;

$$\delta v_1 = \frac{E_i d}{2} \left[ \frac{e^{(s+j\omega_0)t} + j\phi}{2 + \frac{1}{2} \left( j + \frac{s}{\omega_0} \right)} + \frac{e^{(s-j\omega_0)t} - j\phi}{2 + \frac{1}{2} \left( -j + \frac{s}{\omega_0} \right)} \right]$$

Fortunately for the oscillator parameters involved we can make the assumption $|s| \ll |\omega_0|$ which greatly reduces this equation. For the above approximation we obtain;

$$\delta v_1 \sim \frac{E_i d}{4} \left[ \frac{e^{(s+j\omega_0)t} + j\phi + e^{(s+j\omega_0)t} - j\phi}{(1 + \frac{s}{2\omega_0})} \right]$$

or

$$\delta v_1 \sim \frac{\delta v_o}{(2 + \frac{s}{\omega_0})} \quad -(75)$$

If the transfer function for changes in the envelope is defined as $F_1(s)$ for the frequency selective arm we can write;

$$F_1(s) = \frac{\delta v_1}{\delta E_1} = \frac{1}{(2 + \frac{s}{\omega_0})} \quad -(76)$$

where $\delta V_1$ is the amplitude of $\delta v_1$ and $\delta E_1$ is the amplitude of $\delta v_0$.

If the Laplace transforms of $\delta V_1$ and $\delta E_1$ are $L_1(s)$ and $L(s)$ respectively we can write,

$$L_1(s) = \frac{L(s)}{2 + \frac{s}{\omega_0}} \quad -(77)$$

In order to evaluate $L(s)$ in terms of the circuit constants
we must obtain a relationship for the amplitude sensitive arm of
the bridge of figure (15) which consists of the lamps R and resistor
R. In the steady state for the high gain amplifier, the lamp R
had a resistance $R_0$ and $R_2$ was approximately $R_2 \approx R_0$. The power
supplied and hence radiated in the steady state was thus;

$$W_0 = P_0 = \frac{E_1^2}{8R_0} \quad --(78)$$

where $E_1$ is the peak voltage given in equation (70). Upon perturbation
the lamp temperature will vary by a small amount,

$$\theta = \theta_0(1+x)$$

where $x$ is the small time varying parameter. Similarly the lamp
resistance will vary as;

$$R = R_0(1+y)$$

where $y$ is a small time varying parameter. If the perturbation in $R$
occurs from switching the resistance $\epsilon R_0$ into the circuit at time $t=0$,
we can write the time function for the change in $R$ as;

$$\delta R = \epsilon R_0 h(t)$$

where $h(t)$ is the unit step function. Upon perturbation the power
supplied to the lamp, $W$ becomes;

$$W = W_0 + \delta W = \frac{(E_1 + \delta E_1)^2 \{ R_0(1+y) \}}{2(R_2 + \delta R + R_0(1+y))^2} \quad --(79)$$

Assuming a small perturbation such that $\epsilon \ll 1$ this can be approximated
by the binomial expansion as;

$$\delta W \approx W_0 \left[ \frac{2\delta E_1}{E_1} - \epsilon h(t) \right] \quad --(80)$$
The power radiated by the lamp was given in equation (55) as;

\[ P = P_0 + \theta_0 x G_T \]

where \( G_T \) was the differential thermal conductance and \( P_0 \) is the steady state radiated power. The variation in the radiated power is thus;

\[ \delta P = x \theta_0 G_T \quad \text{(81)} \]

The thermal heat capacity of the filament has been defined previously as \( C_T \) so that we can write the power balance equation for the lamp as;

\[ \frac{d}{dt} [C_T \theta_0 (1+x)] = \delta W - \delta P \quad \text{(82)} \]

which can be evaluated by substitution from equation (80) and (81) to obtain,

\[ C_T \theta_0 \frac{dx}{dt} + G_T \theta_0 x = \frac{2P_0}{E_1} \delta E_1 - P_0 \epsilon h(t) \quad \text{(83)} \]

If the Laplace transforms of \( \theta_0 x \) and \( \delta E_1 \) are \( L_x(s) \) and \( L(s) \) respectively the transform equation for (83) is

\[ L_x(s) \{ C_T s + G_T \} = \frac{2P_0}{E_1} L(s) - \frac{P_0 \epsilon}{S} \quad \text{(84)} \]

The temperature coefficient of resistivity for the filament material has been defined as \( \gamma \), and it was shown in equation (66) that

\[ m_0 = \frac{\gamma P_0}{G_T} \quad \text{(66)} \]

Substituting equation (66) in (84) and letting \( \omega_T = G_T/C_T \) we obtain,
\[
L_x(s) = \frac{w_1 m_0}{Y(s+w)} \left\{ \frac{2}{E_1} L(s) - \frac{\xi}{s} \right\}
\]  

The voltage output from the thermal arm of the bridge is \( v_2 \) in the steady state and will change in response to \( \delta v_0 \) to;

\[
v_2 + \delta v_2 = \frac{(v_0 + \delta v_0)(R_2(1+y) + \delta R)}{R_2 + R_0(1+y) + \delta R}
\]  

For small perturbations and noting that \( R_2 \approx R_0 \) this can be approximated as;

\[
\delta v_2 \approx \frac{1}{2}[\delta v_0 + \frac{1}{2} v_0(y + \xi h(t))]
\]

Noting that \( y = y \theta_0 x \) by definition, and writing \( \delta v_2 \) as the change in the envelope of \( \delta v_2 \), we obtain,

\[
\delta V_2 \approx \frac{1}{2}[\delta E_1 + \frac{1}{2} E_1(\gamma \theta_0 x + \xi h(t))]
\]

from which we can write the transform equation if we write \( L_2(s) \) as the transform of \( \delta V_2 \).

\[
L_2(s) = \frac{1}{2} \left[ L(s) + \frac{E_1(\gamma L_x(s) + \xi)}{s} \right]
\]

In the above \( L(s) \) is the transform of \( \delta E_1 \) and \( L_x(s) \) the transform of \( \theta_0 x \).

From the circuit of figure (15) we see that before perturbation,

\[
v_0 = A(v_1 - v_2)
\]

and after perturbation this would become

\[
v_0 + \delta v_0 = A(v_1 + \delta v_1 - v_2 - \delta v_2)
\]
from which the variation term is;

\[ \delta v_o = A(\delta v_1 - \delta v_2) \]

Since \( A \gg 1 \) we see that \( \delta v_1 \approx \delta v_2 \) or \( \delta V_1 \approx \delta v_2 \). Thus the transforms will be approximately equal.

\[ L_1(s) \approx L_2(s) \quad -(89) \]

Solving equations (89), (88), (85) and (77) for \( L(s) \) we obtain the transform of the output disturbance for the perturbation \( \epsilon R_0 h(t) \) as;

\[ L(s) \approx -\frac{E_1 \varepsilon}{2s} \left[ \frac{s^2 + s\{w_T(1-m_o) + 2w_T + 2w_Tm_o(1-m_o)\}}{s^2 + s w_T(1+m_o) + 2w_Tm_o} \right] \quad -(90) \]

Equation (90) is seen to have three poles which are located at the roots of the denominator. \( s = 0 \) and \( s = s_1, s_2 \) where,

\[ s_1, s_2 = -\frac{(1+m_o)w_T}{2} \pm j \sqrt{\frac{2w_Tm_o - \frac{(1+m_o)^2w_T^2}{4}}{2}} \quad -(91) \]

or abbreviating

\[ s_1, s_2 = \alpha + jw_m \]

where

\[ \alpha = -\frac{(1+m_o)w_T}{2} \]

and

\[ w_m = \sqrt{\frac{2w_Tm_o - \frac{(1+m_o)^2w_T^2}{4}}{2}} \quad -(92) \]

The existence of a negative \( \alpha \) means that the poles of \( L(s) \) will all lie in the left hand half of the \( s \) plane. This will ensure absolute stability in that the transient will die out in a finite time. Formal stability in terms of the pole locations is often benificial as a pair of poles which are located close to the \( jw \) axis in the left half plane, correspond to a lightly damped sinusoid
which may be inadmissible where the amplitude is sufficient to seriously alter the steady state output. From equation (92) we see that since \( m_0 \) is small, \( \alpha \) will be correspondingly small with an expected poor transient response. For actual "squeeging" to exist for small perturbations, the constant \( m_0 \) must have a value approaching \( m_0 = -1 \) which of course is not possible for devices which exhibit a positive temperature coefficient of resistance.

The transient response can be found by taking the inverse transform of equation (90). Using the method of residues\(^{(15)}\) at the three poles \( s = 0, s_1, \) and \( s_2, \) the time function can be obtained as;

\[
\delta E_t = -\frac{E_1 \varepsilon}{2 \omega_m} e^{\alpha t} \left[ \left( \frac{1}{2} - m_0 - \frac{1}{2m_0} \right) \omega_m + 2 \omega_m \right] \sin \omega_m t
\]

\[+ \left( 2 - \frac{1}{m_0} \right) \omega_m \cos \omega_m t \]

\[= \frac{E_1 \varepsilon (1 - m_0) h(t)}{2m_0} \]

In the analysis we have already assumed that \( \omega_0 \gg \omega_m. \) Employing this restriction to equation (93) we obtain the approximation

\[
\delta E_t \approx -\frac{E_1 \varepsilon \omega_0}{\omega_m} e^{\alpha t} \sin \omega_m t - \frac{E_1 \varepsilon (1 - m_0)}{2m_0} h(t)
\]

For normal oscillator frequencies the constant term of equation (94) can be ignored because of its relative magnitude. The variable part of equation (94) extrapolated back to \( t=0 \) would be

\[
|\delta E_t| = \frac{E_1 \varepsilon \omega_0}{\omega_m}
\]

and would take the form of a damped sinusoid with the frequency \( \omega_m, \) dying out with the time constant \( T = \frac{\alpha}{2} \) where \( \alpha \) and \( \omega_m \) are given by equations (92).
The transfer function $F_2(s)$ for changes in the output envelope with relative changes in the lamp resistance $\delta R/R_0$ can be written from equation (90) as:

$$F_2(s) = \frac{L(s)}{L_3(s)} = -\frac{E_1}{2} \left[ \frac{s^2 + s(w_T(1-m_o) + 2\omega_o) + 2\omega_o w_T(1-m_o)}{s^2 + s w_T(1+m_o) + 2\omega_o w_T m_o} \right]$$

where $L_3(s)$ is the Laplace transform of the relative change in $R$. The "enhancement factor" which is defined in most literature as the relative change in the output for relative changes of the input can be found for sinusoidal variations of the resistor $R$ by writing $s = j\omega$ in (95) as:

$$\frac{\delta E_1/E_1}{\delta R/R_0} = -\frac{1}{2} \left[ \omega^2 - j\omega[w_T(1-m_o) + 2\omega_o] - 2\omega_o w_T(1-m_o) \right]$$

The maximum enhancement will occur for the real frequency corresponding to the poles of equation (96) which is:

$$\omega^2 \approx 2m_o \omega_w \omega_T \approx \omega_m^2$$

Upon substitution of this value in equation (96) we may write the approximate "enhancement factor" as

$$\left| \frac{\delta E_1/E_1}{\delta R/R_0} \right| \approx \frac{\omega_o}{\omega_w(1+m_o)}$$

Actually we could expect that the true magnitude of the enhancement would be somewhat less than this value due to neglected dissipation in the capacitors and other components and the fact that the gain of the amplifier is not really infinite. The enhancement would
however be expected to be unusually large at high oscillator frequencies. Although extremely linear amplifiers do cause the oscillator to behave poorly with respect to its transient response, the enhancement at high oscillator frequencies is always much better than is predicted by this theory. In fact, the transient response usually improves with increasing oscillator frequency \( \omega \) rather than become worse as is predicted by the theory.

(4) Effect on Transient Response for Nonlinear Amplifier

It was noted in the preceding section that transient disturbances die out much more rapidly than is predicted by the linear amplifier theory especially at higher oscillator frequencies. It is known that small amounts of nonlinearity will prevent the oscillation amplitude from building up indefinitely by effectively altering the gain and thus creating a new steady state operating point. The analysis is thus repeated including the effect of a small nonlinearity present in the operational amplifier.

In practice the highly stabilized amplifier used is characterized by a range which is relatively free from distortion followed by a critical level often referred to as the power point of the amplifier. After this critical level is reached the output is highly nonlinear and usually almost independent of input voltage increases. Below the power point however, the nonlinearity increases very slowly and can be closely approximated by a few terms of a power series such as;

\[
A v_{in} = a_1 v_o + a_2 v_o^2 + a_3 v_o^3 + \ldots \ldots \ldots \ldots
\]

where \( A \) is the amplifier gain, \( v_{in} \) is the amplifier input voltage, and \( v_o \) is the amplifier output voltage. The constants \( a_1, a_2, a_3 \ldots \ldots \)
will vary depending on the amount and type of nonlinearity. In the closed loop operation, the output voltage will contain distortion terms and will be of the form;

\[ v_o = E_1 \cos(\omega_o t + \phi) + D_2 E_1 \cos(2\omega_o t + \phi_1) + D_3 E_1 \cos(3\omega_o t + \phi_2) + \ldots \]

where \( D_2, D_3, \ldots \) are the fractional distortions at the various harmonic frequencies of the oscillator natural frequency \( \omega_o \). Even power nonlinearities in the amplifier will contribute a d.c. term and even harmonics to the output, while odd power nonlinearity will contribute a term at the fundamental frequency plus odd harmonics. Since we are concerned with terms which will limit the amplitude of the output, we will deal only with an odd power nonlinearity and in its simplest form — the cubic. Let us assume then that the amplifier can be represented by the approximation

\[ A_{\text{in}} \approx v_o + bv_o^3 \quad \text{(98)} \]

and for the steady state the output voltage from the oscillator will contain a third harmonic term

\[ v_o = E_1 \cos(\omega_o t + \phi) - D_3 E_1 \cos(3\omega_o t + \phi_2) \quad \text{(99)} \]

where \( D_3 \) is the fractional distortion of the output voltage at the frequency \( 3\omega_o \). The oscillator natural frequency is altered somewhat by this additional term, but as long as \( D_3 \ll 1 \) the change will be insignificant. The approximate amplifier input can be evaluated as;

\[ v_{\text{in}} \approx \frac{E_1}{A} \left(1 + 3bE_o^2\right) \cos(\omega_o t + \phi) - \frac{D_3E_1}{A} \cos(3\omega_o t + \phi_2) + \frac{bE_o^3}{A^4} \cos(3\omega_o t + 3\phi) \quad \text{(100)} \]

The Wien Bridge circuit must in effect adjust slightly for this new condition. We can account for this change by allowing \( k \) to vary.
slightly from previous value of \( k = 2 \), to a new value \( k = 2(1 + 2\delta_1) \)
where \( 2\delta_1 \ll 1 \).

The steady state transfer function \( T_1(jw) \) for the Wien Bridge for the new value of \( k \) is simply

\[
T_1(jw) = \frac{\frac{1}{2} k}{\frac{1}{2}(k+2) + \frac{1}{2}\left[\frac{w}{w_0} - \frac{w_0}{w}\right]} - \frac{1}{2} \\
\approx \frac{1}{2}
\left[\frac{1 + \delta_1}{1 + \frac{(1-\delta_1)}{4} j\left(\frac{w}{w_0} - \frac{w_0}{w}\right)}\right] - 1
\]

\((101)\)

For the term at the fundamental frequency \( w_0 \) this reduces to,

\[
T_1(w_0) \approx \frac{\delta_1}{2}
\]

\((102)\)

while for the term at the third harmonic frequency,

\[
T_1(3w_0) \approx -\frac{e^{j\pi^2}}{\sqrt{13}}
\]

\((103)\)

where \( \alpha_2 = \tan^{-1}\left(\frac{3}{2}\right) \)

Since the input to the bridge is given by equation (99) we can find a second value for \( v_{in} \), which is the bridge output,

\[
v_{in} = \frac{1}{2} \delta_1 E_1 \cos(\omega_0 t + \phi) + \frac{D_3 E_1}{\sqrt{13}} \cos(3\omega_0 t + \phi_2 + \alpha_2)
\]

\((104)\)

Equating equations (104) and (100) to evaluate the unknown parameters we find;

\[
\text{a)} \quad \frac{\delta_1 E_1}{2} = \frac{E_1}{A} \left(1 + \frac{3bE_1^2}{4}\right)
\]

or \( \delta_1 = \frac{2}{A} \left(1 + \frac{3bE_1^2}{4}\right) \)

\((105)\)
For the case of the high gain amplifier where $A \gg 1$ the above can be approximated as

$$D_3 \sim \frac{b\sqrt{13} E_1^2}{4A} \quad \text{and} \quad (\phi_2 + \alpha_2) \sim 3\phi$$  \hspace{1cm} -(106)$$

which when combined with equation (105) yields;

$$\delta_1 \sim \frac{6D_3}{\sqrt{13}}$$  \hspace{1cm} -(106A)$$

If the oscillator is again subjected to a perturbation in the lamp resistance as for the previous analysis, the oscillator output will again be modulated. The third harmonic term in the output will also be modulated in a similar manner.

If the output varies about the steady state by an amount $\delta v_o$ the output will thus be;

$$v_o + \delta v_o = (E_1 + \delta E_1) \cos(\omega_o t + \phi) - (D_3 + \delta D_3)(E_1 + \delta E_1) \cos(3\omega_o t + \phi_2)$$  \hspace{1cm} -(107)$$

where $\delta E_1$ is again a function of time as defined in equation (73).

The amplifier input of figure (15) and hence the bridge output voltage, is given from equation (98) as;

$$v_{in} = \frac{v_o}{A} + \frac{b}{A} v_o^3$$  \hspace{1cm} -(98)$$

For the term involving the fundamental frequency $\omega_o$ in equation (107) this is approximately;

$$[v_{in} + \delta v_{in}]_{\omega = \omega_o} = \frac{E_1 + \delta E_1}{A} \left[1 + \frac{3b}{4} (E_1 + \delta E_1)^2\right] \cos(\omega_o t + \phi)$$
and hence

\[ \delta V_{\text{in}} \bigg|_{\omega = \omega_0} \propto \frac{\delta E}{A} \left[ 1 + \frac{9b}{4} \frac{E_1^2}{E} \right] \tag{108} \]

where \( \delta V_{\text{in}} \) is the change in the envelope of \( \delta v_{\text{in}} \) defined as

\[ \delta v_{\text{in}} = \delta V_{\text{in}} \cos(\omega_0 t + \phi). \]

Substituting the value of "b" from equation (106) in (108) yields;

\[ \delta V_{\text{in}} \bigg|_{\omega = \omega_0} \propto \delta E \frac{9D^3}{14I^2} \tag{109} \]

A second value for \( \delta V_{\text{in}} \) is seen from figure (15) to be

\[ \delta V_{\text{in}} = \delta V_1 - \delta V_2 \tag{110} \]

The steady state transfer function \( T(j\omega) \) for the frequency selective arm of the bridge which is needed to evaluate \( \delta V_1 \) is simply the first term of equation (101). Thus

\[ T(j\omega) = \frac{\frac{1}{2}(1 + \delta_1)}{1 + \frac{(1-\delta_1)}{4} \left[ j\omega \pm \frac{\omega_0}{j\omega} \right]} \tag{111} \]

Again for the complex frequencies \( j\omega = (s \pm j\omega_0) \) associated with the oscillator output, this becomes

\[ T(s + j\omega) + T(s - j\omega) = \frac{\frac{1}{2}(1 + \delta_1)}{1 + \frac{(1-\delta_1)}{4} \left[ s \pm j\omega_0 \right]} \left[ \frac{\omega_0}{w_o} \right] \]

\[ + \frac{\frac{1}{2}(1 + \delta_1)}{1 + \frac{(1-\delta_1)}{4} \left[ s \mp j\omega_0 \right]} \left[ \frac{\omega_0}{w_o} \right] \]

\[ \approx \frac{\frac{1}{2}(1+\delta_1)}{1 + \frac{(1-\delta_1)}{2} \frac{s}{\omega_0}} \tag{112} \]
where it has been assumed that $|s| \ll |w_0|$.

The transfer function $F_3(s)$ for changes in the envelope through the frequency selective arm is thus defined as,

$$F_3(s) = \frac{\delta V_1}{\delta E_1} = \frac{\frac{1}{2}(1 + \delta_1)}{1 + \frac{(1-\delta_1)s}{2} \omega_0}$$  \hspace{1cm} \text{--(113)}

If we again define $L(s)$ as the Laplace transform of $\delta E_1$, then $L_4(s)$, the Laplace transform of $\delta V_1$, is given by;

$$L_4(s) = L(s) F_3(s)$$  \hspace{1cm} \text{--(114)}

The output from the amplitude sensitive arm of the bridge is again defined by equation (88) and (85) as;

$$L_2(s) = \frac{1}{2} L(s) + \frac{1}{2} E_1 (\gamma L_X(s) + \frac{\epsilon}{s})$$  \hspace{1cm} \text{--(88)}

where;

$$L_X(s) = \frac{\omega_1 \omega_0}{\gamma(s+\omega_1)} \left[ \frac{2L(s)}{E_1} - \frac{\epsilon}{s} \right]$$  \hspace{1cm} \text{--(85)}

If we now define $L_5(s)$ as the Laplace Transform of $\delta V_{in}$ we can write from equation (109) and (110);

$$L_5(s) = L(s) \frac{\delta V_1}{2} = L_4(s) - L_2(s)$$  \hspace{1cm} \text{--(115)}

and we can solve equations (115),(85),(88),(114) and (113) for $L(s)$ to yield,

$$L(s) = \left[ \begin{array}{c} \frac{E_1 \epsilon}{2s} \left[ 1 - \frac{m \omega_T}{s+\omega_T} \right] \\
\frac{1 + \delta_1}{1 + (1-\delta_1)s} \left[ 1 - \frac{\gamma \omega_T}{s+\omega_T} \right] \\
1 + \frac{(1-\delta_1)s}{2\omega_0} \end{array} \right]$$  \hspace{1cm} \text{--(116)}$$
Neglecting terms in $\delta_1^2$ and higher this can be written as the ratio of two polynomials in $s$.

$$L(s) = \frac{\epsilon F}{2} \left[ \frac{s^2 + s [(1-m_0) \omega_T + 2(1+\delta_0) \omega_0] + 2(1+\delta_0)(1-m_0) \omega_0 \omega_T}{s^2 + s [(1+m_0)(1-3\delta_0) \omega_T + 4 \omega_0 \delta_1] + 2 \omega_0 \omega_T \delta_0 (1-2\delta_0) + 2 \delta_0^2} \right]$$

Since $D_3$ is small $\delta_1$ is also small and will only have a significant influence on the coefficient of $s$ in the denominator. Hence the above can be approximated as:

$$L(s) \simeq \frac{\epsilon F}{2} \left[ \frac{s^2 + s (1-m_0) \omega_T + 2 \omega_0^2 + 2(1-m_0) \omega_0 \omega_T}{s^2 + s (1+m_0) \omega_T + 4 \omega_0 \delta_1^2 + 2 m_0 \omega_0 \omega_T} \right]$$

where $\delta_1 \ll |\omega_0|$.

Equation (117) has three poles, $s=0, s=s_3$ and $s=s_4$ given by the roots of the denominator of equation (117). Thus;

$$s_3, s_4 = \alpha_l + \omega_{ml}$$

where $\alpha_l$ and $\omega_{ml}$ are defined as;

$$\alpha_l = \frac{(1+m_0) \omega_T + 4 \omega_0 \delta_1}{2}$$

and

$$\omega_{ml}^2 \sim 2 \omega_0 \omega_T m_0 - \left[ \frac{(1+m_0) \omega_T + 4 \omega_0 \delta_1}{2} \right]^2$$

For normal oscillator frequencies where $\omega_0 > \omega_T$, this reduces to approximately the same value as for the linear amplifier.

$$\omega_{ml}^2 \sim 2 \omega_0 \omega_T m_0 = \omega_m^2$$

We should note however, that for increased nonlinearity and hence increased $\delta_1$, the second term of equation (120) would become more important.
and the modulation frequency would be decreased.

Since $\alpha_1$ is negative for real values of the parameters $m_o, \omega_T, \delta_1$, and $\omega_0$, the transient will decrease with time. Furthermore since $|\alpha_1|$ is increased by the term $2\omega_0 \delta_1$, the time constant with which the transient decreases will be much shorter especially for the higher oscillator frequencies. The actual transient $\delta E_1$ can again be obtained from the inverse transform of equation (117) as;

$$\delta E_1 = - \frac{E_1 \xi}{2} \frac{(1-m_0)}{m_o} h(t) - \frac{E_1 \xi}{2 \omega_{ml}} e^{\alpha_1 t} \left[ (2\omega_0 + \frac{1}{2} - m_0 - \frac{I}{2m_0} \omega_T) \sin \omega_{ml} t 
+ (2 - \frac{1}{m_0}) \omega_{ml} \cos \omega_{ml} t \right]$$  

which is identical to the result obtained for the linear amplifier except that $\alpha$ has been replaced with $\alpha_1$ and $\omega_m$ has been replaced with $\omega_{ml}$. The approximate transient for $\omega_0 \gg \omega_T$ can again be written.

$$\delta E_1 \sim - \frac{E_1 \xi}{\omega_{ml}} e^{\alpha_1 t} \omega_0 \sin \omega_{ml} t - \frac{E_1 \xi}{2} \frac{(1-m_0)}{m_o} h(t)$$  

The time constant with which the transient dies out is the reciprocal of $\alpha_1$ and is thus;

$$\tau_r \sim \frac{2}{(1+m_o)\omega_T + 4\omega_0 \delta_1}$$  

The value of $\Delta E_1$ which is the magnitude of $\delta E_1$ extrapolated back to $t=0$ will be unchanged from the case of the linear amplifier. However, since the time constant will be much shorter for the nonlinear amplifier, the associated first peak of the sinusoid will be much smaller than for the linear amplifier. In figure (16) the oscillator output response is shown for $\delta R = -E_R h(t)$ which is the negative of
the result obtained in equation (122) and was caused by closing the switch in figure (15) at time $t=0$.

where the variable part of $\delta E_1$ is given by;

$$\delta E_1 \approx \frac{E_1 \xi}{\omega_{ml}} e^{\alpha_1 t} \omega_o \sin \omega_{ml} t$$  \hspace{1cm} \text{--(125)}$$

The variable part will thus reach a value $\delta E_1 \text{ peak}$ shown in figure (16) at some time $t = t_1$. For this condition we can solve for $t_1$ by differentiating equation (125) and setting the result equal zero to yield:

$$\frac{d}{dt}[\delta E] = 0 = \frac{E \xi \omega_o}{\omega_{ml}} [\alpha_1 e^{\alpha_1 t_1} \sin \omega_{ml} t_1 + \omega_{ml} e^{\alpha_1 t_1} \cos \omega_{ml} t_1]$$

thus

$$t_1 = \frac{1}{\omega_{ml}} \tan \left[\frac{-1 [\omega_{ml}]}{-\alpha_1}\right]$$  \hspace{1cm} \text{--(126)}$$

The value for $\delta E_1 \text{ peak}$ can also be calculated for the value of $t_1$ as;

$$\frac{\delta E_1 \text{ peak}}{\delta E_1} = \frac{E \xi \omega_o}{\sqrt{2 \omega_o \omega_{ml}}} e^{\alpha_1 t_1}$$  \hspace{1cm} \text{--(127)}$$
where $t_1$ is given by equation (126).

Since the time constant will be larger for the linear case, the value of $E_{1\text{peak}}$ will be greater than for the case of the nonlinear amplifier. In addition if the first peak is large, the nonlinearity will tend to limit the increasing amplitude peak. The most important result of the nonlinearity is that the time constant will decrease to an extremely low value at the higher oscillator frequencies as is shown by equation (124). For increased nonlinearity the frequency $\omega_m$ would also become lower and the time $t_1$ given by equation (126) would increase while the time constant $T_1$ decreased. The net result would also decrease the amplitude of the first peak.

The response of the system to sinusoidal variations in the lamp resistance can be found in the same manner as for the linear amplifier. For a variation $\delta R = \xi_0 e^{j\omega t}$ we obtain;

$$\delta E_1 = \frac{E_0 \xi_0}{2} e^{j\omega t} \left[ \frac{\omega^2 - j\omega \xi_0 (1-m_0) \omega_T + 2 \omega \xi_0^2 - 2 (1-m_0) \omega \omega_T}{\omega^2 - j\omega \xi_0 (1+m_0) \omega_T + 4 \xi_0^2 \omega^2 - 2 m_0 \omega \omega_T} \right]$$  \hspace{1cm} (128)

For a range of oscillator frequencies where $\omega_o \gg \omega_T$ the enhancement will be a maximum at the frequency,

$$\omega^2 \approx 2m_0 \omega_o \omega_T$$

and the "enhancement factor" will thus be;

$$\left| \frac{\delta E_1}{E_1} \right| \left| \frac{\delta R}{R_o} \right|_{\omega = \omega_m} \propto \frac{\omega_o}{(1+m_0) \omega_T^2 + 4 \delta_1 \omega_o}$$  \hspace{1cm} (129)

The enhancement for the nonlinear amplifier case is thus improved by the factor $4\delta_1 \omega_o$ in the denominator as can be seen by comparison of equations (129) and (97).
The analysis presented has been entirely for perturbations of the lamp resistance $\delta R$. The analysis can be extended to variations in any of the closed loop parameters through the use of the basic oscillator equation (16)

$$\frac{k}{k+2} \frac{R_0}{R_0 + R_2} = \frac{1}{A}$$

and the chain rule. For example if the transfer function for changes in output for relative changes in the lamp resistance is $F_2(s)$, then an expression for the output voltage envelope corresponding to a variation in the amplifier gain $\delta A/A$ would be

$$\delta E_1 \approx \frac{\delta A}{A}(s) \frac{3R_0}{A} \frac{A}{R_0} F_2(s)$$

$$= \frac{\delta A}{A}(s) \frac{4}{A} F_2(s)$$

The enhancement of variations of amplifier gain would thus be reduced by the factor $4/A$ which is in agreement with the general concept of the use of the bridge circuit. Since the value of $\delta_1$ decreases proportional to $A$ the enhancement of variations of amplifier gain should be independent of $A$ for high frequencies and the condition that $A \gg 1$. 
VI THE EXPERIMENTAL CIRCUIT

(1) The Basic Oscillator

In order to evaluate the theory presented in the preceding sections, an oscillator was constructed from which the transients could be measured. To keep the transients as large as possible, the amplifier used was constructed as linear as was possible. The basic oscillator described in the theory can be drawn in a block diagram form such as that of figure (17)

![Figure (17)](image)

The oscillator consists of the lamp Bridge Arm $N(E_1)$, the Frequency Selective Arm $\beta(\omega)$, and the Amplifier $A$ which contains a small amount of third harmonic distortion. The summing amplifier shown can be a part of the amplifier $A$ and has unity gain.

(2) The Frequency Selective Network

The frequency selective network shown in figure (18) was discussed in sections III and V.

![Figure (18)](image)
The values of the components $R_1$ and $C$ are to a large extent governed by the input and output impedances of the amplifier. The value of $R_1$ for the low frequency end of the tuning range must be much smaller than the input impedance of the amplifier. Similarly, at the high end of the tuning range, the value of $C$ must be much larger than the input capacitance of the amplifier. The total impedance of the frequency selective network must also be high enough not to severely load the amplifier. In particular the network impedance should be much larger than the amplifier output impedance for the analysis given. These effects can be reduced by using cathode follower inputs and output for the amplifier, but should not be ignored in the design.

(3) The Thermal Bridge Arm

The thermal bridge arm contained two tungsten lamps as shown in figure (19).

![Figure (19)](image)

By the inclusion of $R_5$, the resistor $R_2$ can be adjusted exactly to $R_2 = R_0$ and still maintain the slight bridge misbalance necessary for oscillation. The value of $R_5$ should however, be much larger than $R_2$ or $R_0$. The two lamps used for the variable resistance $R$ should have sufficiently high resistance not to load the amplifier output and yet still have a characteristic which would enable them
to be used above their transition region for low oscillator output voltages. The switch $Sw$ and resistor $ER_0$ were included as a source of the perturbation $ER = -ER_0 h(t)$.

(4) **The Linear Amplifier**

The high gain amplifier must consist of at least two stages in order to achieve the zero net phase shift required by the analysis. As mentioned earlier the output impedance of the amplifier must be very low in order that the Wien Bridge circuit does not overload the amplifier. This can be easily accomplished by using a heavy duty cathode follower for the output stage. The high gain and zero net phase shift can be obtained from any simple two stage preamplifier. The frequency response of the entire amplifier should be flat from very low frequencies to frequencies well above those used in the tests. The net phase shift of the amplifier should be kept close to zero degrees although a small phase shift will not greatly alter the oscillation frequency. In order to minimize the harmonic distortion and decrease the amplifier output impedance, the amplifier employed approximately $20\text{db}$ of overall negative voltage feedback, and operation was confined to a region of about one quarter of its designed maximum output level.

(5) **The Differential Amplifier**

The summing amplifier used should be as free from common mode effect as possible. Several different types of differential amplifier circuits are discussed in the literature (17),(18). The circuit selected, and designed consisted of a double triode $T_1$ with a common cathode consisting of a triode $T_2$ and its cathode resistor $R_k$. 
The combination of triode $T_2$ and resistor $R_X$ provided an effective A.C. common cathode resistance of $r_{p2} + (1+\mu_z)R_X$ for the double triode $T_1$. Here $r_{p2}$ is the plate resistance of $T_2$ and $\mu_z$ is mhu of $T_2$. This provided a minimum common mode voltage and a maximum input impedance for the differential amplifier. A double triode should be used for the tube $T_1$ to minimize differences in characteristics between the two inputs. This amplifier was constructed as a part of the total high gain amplifier $A$.

(6) The Envelope Detector

Although this piece of equipment was not a part of the actual oscillator, it was used wherever the time constant permitted to detect the modulation frequency of the transient and amplify the envelope to a level suitable to drive a Beckman Counter. The block diagram of the detector is shown in figure (20).

![Block diagram of the envelope detector](image)

Figure (20)

The circuit used consisted of an indium bonded diode type 1N100 followed by a low pass non-tapered R-C filter which comprised the actual detector. The detected envelope was then amplified by the amplifier $A_4$ and clipped at approximately two volts to supply the desired amplitude for the counter. The low pass filter was a non-tapered four section R-C filter designed to eliminate any carrier frequency above 190 cps. The limiter consisted of a pair of reverse biased diodes which were adjusted to clip at two volts peak to peak.
VII EXPERIMENTAL OUTLINE

(1) General Outline

The experimental portion of the thesis was carried out to evaluate the various parameters and to verify the theoretical results obtained in the analysis. The oscillator circuit was designed and constructed to meet the requirements indicated in the previous chapter. The transient waveform of the oscillator was then measured for a perturbation of the lamp resistance at various oscillator frequencies and amplitudes.

The static characteristics of the lamp bridge used in the oscillator were measured and the experimental values were compared with those predicted by the theory. The time constant due to the thermal inertia of the lamp was measured and the result was used in calculating the expected transient response for the oscillator.

A study of the low frequency response of the lamp bridge was also made. The results obtained were used to check the result of equation (60) with regard to the unwanted output at the bridge balance point, and the variation of the unwanted output with bridge input voltage and frequency.

(2) Measurement of Static Lamp Characteristics

The static current-voltage characteristic was measured for the two Westinghouse ten watt 250 volt lamps connected in series. The voltage supply used was a John Fluke Stabilized Power Supply model 407 and the voltage was measured with a John Fluke Digital Voltmeter. A standard 0.5% laboratory d.c. milliammeter was used to measure the current through the lamps. The power supplied to the lamps and hence
radiated in the steady state and the resistance of the lamps were then
calculated for the various lamp voltages. These results are tab-
ulated in table (1) and are shown plotted in graphs number (1),(2), and (3).

The static current-voltage relationship is shown on graph
number one for the two lamps connected in series. The characteristic
is seen to be composed of a linear region, a transition region, and
an almost straight line region. A graphical analysis of this
characteristic in the region of oscillator operation yields an
approximate curve given by,

\[ E = 0.884 I^{1.64} \]

where \( E \) and \( I \) are the d.c. voltage and current supplied to the lamp
in volts d.c. and m.a.d.c.

Graph number two is a plot of the lamp resistance \( R \) as
a function of the lamp voltage \( E \) which can be approximated by the
straight line relationship

\[ R \approx 900 + 170E \]
in the region of oscillator operation.

The third graph, graph (3), shows the relationship between
the lamp resistance \( R \) and power supplied or radiated in the steady
state. As mentioned in the theory we would expect a straight line
relationship between \( \log R \) and \( \log W \) excepting the low power inputs
where the supplied power has little effect on the lamp temperature.
Graph (3) shows this straight line region quite clearly with a slope

\[ m_0 = 0.226 \]

We also see from graph (3) that there is a linear region for very low
power inputs which corresponds to the region in which the lamp temp-
erature is completely governed by the ambient temperature. The

</table>
curved region which follows is simply the transition region in which the effect of the room temperature plays a decreasing role with increasing power in establishing the filament temperature. Operation below a lamp voltage of two volts would be inadvisable due to these ambient temperature effects on the lamp performance.

It should be noted that since the lamps used were designed and manufactured for illumination purposes, variations between the static characteristics of two identical lamps often exceeds 10%. The characteristics shown apply to the two lamps used in the oscillator and should be accurate within one half of one percent, but will only be typical values for lamps of their general rating and species.

(3) Measurement of Thermal Time Constant

The thermal time constant of the lamps can be measured by connecting the lamp bridge to a constant voltage supply and subjecting the lamp bridge to a small change in operating voltage. The circuit used is shown in figure (21) and enabled the measurement of the variable term on the oscilloscope.

![Oscilloscope Diagram](image)

Figure (21)

At normal oscillator frequencies the lamp will behave in the same manner as it would to a direct current voltage. We can thus replace the alternating constant voltage supply for the regulated d.c.
FIGURE 22
Horiz. Scale 1.0 Sec./ Div.
Lamp Voltage 10 Volts D.C.
power supply shown in figure (21). Resistors $R_7$ and $R_8$ are part of a low resistance potentiometer included to facilitate the change in voltage and to improve the regulation of the power supply. Resistor $R_8$ was adjusted for each bridge voltage to yield approximately a ten percent change in input voltage when switch $s_w$ was closed. Resistors $R_6$ were a matched pair of resistors much higher than the mean lamp resistance and yet much smaller than the oscilloscope input impedance. A value of $R_6 = 10K$ was used. The bridge was initially balanced with switch $s_w$ closed which brings the oscilloscope into the circuit along with the increased voltage. For this condition the oscilloscope trace was along the zero voltage axis. The switch $s_w$ was then opened and after the lamp had reached its new steady state, switch $s_w$ was again closed and the transient noted.

If we let the input voltage to the bridge vary due to a step change $\delta V_o$ to $V_o(l+\xi)$ at time $t=0$ the resistance $R$ will vary as $R_o(l+y)$ as the filament temperature varies as $\theta_o(l+x)$. It can be shown that the bridge output voltage $v_{out} = (v_1 - v_2)$ is given by;

$$v_{out} = V_o(l+\xi h(t)) \left[ \frac{1}{2} - \frac{R_o}{R_o + R_o(l+y)} \right]$$

where $y = 2\xi m_o \left[ 1 - e^{-\omega_{\xi} t} \right] h(t)$

which reduces to the form

$$v_{out} = \frac{V_o m_o}{2} \left[ 1 - e^{-\omega_{\xi} t} \right] (l+\xi) h(t)$$

which is a constant term plus a variable term. When the variable term is separated and measured as in figure (21) we can find the thermal time constant for the lamp bridge $\tau = \frac{1}{\omega_{\xi}}$ by noting the amplitudes of the trace at two instants in time. If the amplitude of the trace
is $V_1$ at time $t_1$ and $V_2$ at time $t_2$ then the time constant would be;

$$\tau = \frac{1}{\omega_T} = \frac{t_1 - t_2}{\ln \frac{V_2}{V_1}} \quad \text{---(130)}$$

The time constant can thus be evaluated by obtaining the difference in time between where the trace crosses two successive or particular graticule lines on the oscilloscope face. The values should be measured close to the steady state where the lamp voltage is close to half the bridge input voltage.

The values for the time constant were found for ten lamp voltages given in table (2). These values are the average values of a successive number of trials. A d.c. amplifier not shown in figure (21) was constructed and used in conjunction with the oscilloscope to provide additional gain especially for low lamp voltages. The oscilloscope was used on d.c. input because of the time constant associated with the coupling capacitors of the oscilloscope on A.C. input.

The time constant due to the thermal inertia of the lamp is plotted as a function of lamp voltage $E$ on graph number four. Figure (22) shows a typical oscillogram taken from the oscilloscope of figure (21) for a lamp voltage at balance of $E = 10$ volts D.C. The values are used later in predicting the expected transient for the oscillator.

(4) Low Frequency Lamp Response

The circuit of figure (23) was constructed using the lamps employed in the oscillator limiter and the bridge output was measured

at balance for low frequencies using a Muirhead Wave Analyser type D 729-B.

![Figure (23)](image)

The resistors $R_6$ were much larger than $R$ and were a matched pair.

Resistor $R_2$ was adjusted for each bridge input voltage to make the
bridge output a minimum. The constant voltage source consisted of
a Hewlett Packard model 200-CD Wide Range Oscillator operating at
a low output and feeding a high power low output impedance amplifier.
The output from the bridge was also fed through an amplifier to an
oscilloscope. An oscillogram figure (24) was taken from the oscillo-
scope for a bridge driving frequency of five cycles per second. The
output is seen from figure (24) to be composed of two frequency com-
ponents of equal amplitude and opposite phase. The first is at the
fundamental frequency of the bridge input voltage and the second
is at the third harmonic; both are shifted by ninety degrees from
the bridge input voltage.

A plot of one of these two frequency components is shown in
graph (5) and the results are tabulated for the two in table (3). The
input voltage was measured with a thermal milliammeter and series
resistor which had been calibrated to read in volts R.M.S.

The theoretical value for the bridge output voltage can
be found from section IV-(3) equation (60) if we note that \( Y = m_0 \frac{G_r}{P_0} \)
and \( P_0 = \frac{E^2}{4R_0} \) where \( \omega_T = G_T/C_T \). The bridge output would thus be

\[
\nu_{out} = \frac{Em_0 \omega_T}{8\sqrt{2}} \left[ \cos 3\omega_0 t - \cos \omega_0 t \right]
\]

The plots of graph (5) vary quite closely as the reciprocal of the
driving frequency \( \omega_0 \) as is indicated by the theory. As a further
check the equation can be evaluated at some bridge voltage say \( E = 10 \)
volts RMS, \( m_0 = 0.226 \) and \( \omega_T \) can be evaluated from table (2) at a
lamp voltage of 5 volts RMS as \( \omega_T = \frac{1}{4.6} \) sec\(^{-1} \). For these
values the output is;

FIGURE 24
Unwanted Bridge Output at a frequency of 5 c.p.s.

GRAPH 5
Third Harmonic Component in milli-volts R.M.S.

Driving Voltage Frequency in c.p.s.
\[ v_{out \, at \, 5 \, cps} = 0.977 \, m. \, volts \, R.M.S. \]
\[ v_{out \, at \, 30 \, cps} = 0.163 \, m. \, volts \, R.M.S. \]

which agrees quite closely to 0.89 m. volts and 0.16 m. volts measured and recorded in table (3).

The magnitude of the unwanted component should thus not be objectionable for oscillator frequencies of five cycles or higher for even extremely high gain amplifiers used in the Wien Bridge Oscillator circuit. Below five cycles per second the unwanted components increase quite rapidly and hence sets a lower limit on the usefulness of the thermal compensator as a control unit.

(5) Transient Oscillator Response

The oscillator circuit was constructed with the value of \( k \) in figure (14) chosen as \( k=2 \). This choice of \( k=2 \) allows the Wien Bridge circuit to operate at the condition of maximum frequency sensitivity. The capacitors \( 2C \) and \( C \) were of a fixed value mica type and were matched for the two to one ratio. These remained constant during all of the tests.

The resistors \( R_1 \) and \( R_{1/2} \) were of the deposited carbon type and were mounted in shielded plug in units to allow changes in oscillator frequency. The values of all the components were adjusted to form balanced pairs. To allow a continual frequency variation, a dual potentiometer was mounted in a shielded plug in unit. Although the tracking was not particularly good on this device it was suitable to obtain the frequencies where hum enhancement occurred. The values of the circuit frequency determining elements are listed with the expected oscillator frequencies.
C = 24140 p.f.

</tbody>
</table>

The dual potentiometer had a value of 0 - 50K, 0 - 25K ohms and would thus tune the above range of frequencies.

The transient was introduced by shorting the small resistance \(6R_0\) in series with the two lamps at a time \(t = 0\). The result obtained was a damped oscillatory transient as shown in figure (25). These transients were produced and measured for various oscillator frequencies and oscillator output levels.

The observed transient waveform can be easily correlated with the theory with the aid of figure (26).

Here the various terms are defined by

\[E_1 = \text{oscillator steady state peak amplitude in peak volts.}\]

\[\Delta E_1 = \text{magnitude of transient extrapolated back to } t = 0 \text{ in peak volts.}\]

\[\delta E_1 = \text{magnitude of first peak of transient in peak volts.}\]

\[f_m = \text{modulation frequency in c.p.s.} = \frac{1}{t_2 - t_1}\]

\[T_1 = \text{time constant of transient wave form in sec.}\]

From equation (93) these terms can be approximated for the linear theory as
FIGURE 25
Oscillator Transient caused by a typical switching disturbance

FIGURE 26
Voltage in peak volts.

E

ΔE

E₁

t₁ t₂ t₃ t. in sec.
\[ \delta E_{1/\text{peak}} \approx \Delta E_1 = \frac{E_1 \delta \omega}{\omega_m} \tag{131} \]

\[ f_m \approx \frac{1}{2\pi} \sqrt{\frac{2m \omega_0 \omega_T}{\delta}} \tag{132} \]

and

\[ \tau_i \approx \frac{2}{(1+m_0)\omega_T} \tag{133} \]

Similarly, where the nonlinearity of the amplifier is accounted for, the terms become,

\[ \delta E_{1/\text{peak}} \approx \frac{E_1 \delta \omega}{\omega_m} \cdot \frac{1}{\tan^{-1}(\tau_i \omega_m)} \tag{134} \]

\[ f_m \approx \frac{1}{2\pi} \sqrt{\frac{2m \omega_0 \omega_T}{\delta}} \tag{135} \]

\[ \tau_i \approx \frac{2}{(1+m_0)\omega_T + 4\omega \delta} \tag{136} \]

The presence of even a minute amount of cubic nonlinearity should have a profound effect on the transient time constant \( \tau_i \), as is seen in equation number (136) while the modulation frequency of the oscillator will remain practically unchanged for small nonlinearities such that \( D < 0.01 \) (eq. 134).

The experimental values for the peak amplitude \( \delta E_{1/\text{peak}} \), the time constant \( \tau_i \), and the modulation frequency \( f_m \) were measured from the transient waveform displayed on a Tektronic Oscilloscope model 536. The oscillator frequency and the modulation frequency were measured on a Beckman Eput and Timer model 7370 wherever the transient time constant would permit its use. The oscillation level
was established by the use of a thermal voltmeter which was constructed from a thermal milliammeter and calibrated to read R.M.S. voltages. The results which are shown tabulated in table (4) are for a step function of resistance $\delta R = -2.018 \, \text{h}(t)$ which was introduced by shorting the 2.018 ohm resistor with a switch at time $t = 0$. The value of $R_2$ which was a carbon potentiometer was adjusted for each oscillator voltage on a resistance bridge so that $R_2 = R_0$. The potentiometer $R_5$ of figure (19) was then adjusted to provide the small misbalance needed to obtain the exact oscillator output voltage. The time constant was evaluated from the time base of the oscilloscope which was checked at low sweep rates with a stop watch and higher sweep rates with the counter and a known frequency signal. The measured values for these readings are shown in graphs numbers (6), (7) and (8). In graph (6) the peak amplitude $\delta E_1 / \text{peak}$ is plotted as a function of the square root of the oscillator frequency. In graph (7) the modulation frequency is shown as a function of the square root of the oscillator frequency, and in graph (8) the transient time constant is shown as a function of the oscillator frequency.

The theoretical results for the oscillator with a linear high gain amplifier were next calculated from equations (131), (132), and (133) and are listed in table (5). The values for $f_0$ are taken from the expected value of $f_0$ for the constants used in each of the plug in frequency determining units. The values of $\epsilon$ and $\omega_n$ are for a resistance change of 2.018 ohm and the time constant given on graph (4). The values for the steady state lamp resistances are given on graph (2) or table (2). The theoretical curves are

</table>
plotted in graphs (9) and (10) for the modulation frequency $f_m$
as a function of the square root of the oscillator frequency and the
amplitude of the peak versus the square root of the oscillator
frequency. Clearly the linear theory does not predict the decrease
in the time constant for increasing oscillator frequency and the
transient peak is larger than is measured. The linear theory does
however, predict the modulation frequency with a reasonable degree of
accuracy.

From graph (8) we see that the measured time constant is
much shorter than is predicted by equation (133) and decreases
quite rapidly with increasing oscillator frequency. The peak value
of the transient apart from being smaller than is expected from the
linear theory, decreases slightly from the straight line predicted
for graph (10) for increasing oscillator frequency.

The small amount of cubic nonlinearity present in the
operational amplifier of the Wien Bridge Oscillator was next measured
for the steady state with the General Radio Wave Analyser. Readings
for low voltage oscillator outputs were inconclusive but for a voltage
output of 10.0 volts R.M.S. it was found that the third harmonic fractional
distortion was approximately $D_3 \approx 1.1 \times 10^{-4}$. Values for $D_3$ for
lower voltages were calculated using this result and the relationship
given by equation (106). The value for $S_1$ can be found from equation
(106A) and equations (134), (135) and (136) can be evaluated in the
same manner as for the linear theory. Equation (134) may be further
approximated for computations as;

</table>
for small nonlinearity such that \((T_1 w_m)^2 \gg 1\). The results are tabulated in table (6) and are plotted in graphs (11) and (12).

From graph (11) we see that the peak amplitude of the transient is somewhat larger than was measured, but it experiences the deviation from the straight line for increasing oscillator frequencies as is found in practice. The deviation of the experimental from the theoretical can perhaps be attributed to two things, first the switching time of the perturbation may not be infinitesimally small as assumed in the analysis, and second the larger peaks will be reduced by the increasing nonlinearity. This mechanism seems to be present in figure (25) for the large transient caused by switching frequencies. All of the increasing peaks are flattened while all of the decreasing peaks are lengthened by the cubic nonlinearity. If these two things were included the result would be a smaller value of \(\delta E_1\) peak which would be in accordance with the experimental results.

From graph (12) the transient time constant \(T_1\) is seen to be markedly changed by the inclusion of the small cubic nonlinearity. In most practical problems this nonlinearity would most certainly be neglected in the first approximation and yet in this case it has a profound effect on the transient response. The experimental values of the time constant are seen to agree quite closely with equation (136) or graph (12).

(6) **Hum Enhancement**

The oscillator constructed was extremely poor with respect

Graph (11)
to disturbances in the output. The chassis was well grounded and the lamp assembly was shock mounted and screened to minimize random variations from being originated from outside the oscillator. Even with these precautions random variations due to internal noise and power hum were present to a small extent for low oscillator output levels where the amplifier nonlinearity was a minimum.

Random noise and power hum could be regarded as a variation of the amplifier gain as the two are probably introduced in the amplifier through resistor and tube noise and A.C. power frequencies in the d.c. power supply. For the case of the amplifier used two harmonics of the power frequency were found to cause a continuous modulation where they provided one of the two components necessary in the output for continuous modulation. For the two frequencies 180 cps and 300 cps corresponding to the third and fifth harmonics of the power frequency, four oscillator frequencies were found where continuous modulation at the frequency $f_m$ occurred. The oscillator frequencies were of course $f_o = (180 \pm f_m)$ and $f_o = (300 \pm f_m)$ where $f_m$ is the expected modulation frequency at the oscillator frequency $f_o$.

It was shown in the theoretical section that sinusoidal variations of the amplifier gain would be reduced by the factor $4/A$ from the case of sinusoidal variations in the lamp resistance $R$ or for that matter sinusoidal variations in the parameter $k$ of the frequency selective arm. From equation (106) we have seen that the distortion is proportional to the reciprocal of the amplifier gain. Hence the enhancement of variations in the amplifier gain will be approximately independent of the gain $A$ so long as $A \gg 1$. 
The most sensitive portion of the oscillator to variations is of course the two feedback loops. Electrical radiation or mechanical vibration could cause a severe disturbance in the output. For this reason these components were particularly well shielded and shock mounted.
VIII CONCLUSION AND SUGGESTIONS

Although we have shown that the simple lamp bridge is an effective long time control for the oscillator amplitude with respect to variations in the amplifier gain, the thermal inertia of the lamp gives the system a poor transient response for any changes in the closed loop. In addition the oscillator's operating region is confined to frequencies above a lower limit indicated in section IV-(3). Below this lower limit, the lamp resistance will vary over the individual cycle and hence distort the output. The latter difficulty is inherent in this type of automatic level control, but the former can be improved by the presence of odd power nonlinearity in the operational amplifier. The presence of this nonlinearity is extremely effective and unless the amplifier contains a third harmonic distortion greater than 100db down, it would be impossible to obtain a steady state output as noise and radiation would cause the output to be swamped by transients.

In general this type of automatic level control is inexpensive and quite simple to build. The time constant for the thermal bridge should be kept as short as possible consistent with the condition that it is long with respect to the period of the oscillation frequency. The transient response can be improved by increasing the value of the constant \( m_o \) which would mean choosing a different type of lamp or thermal device. For the thermistor of figure (11) a similar experimental value for \( m_o \) would be \( m_o \approx -2.56 \) and if this device was used in its appropriate bridge, the transient output would be improved. From equations (134), (135), and (136) we see that for
a larger $m_0$, the peak $\delta E_1$ is smaller, the frequency $f_m$ is higher, and the time constant of the transient $\tau_1$ is shorter at the lower oscillator frequencies $f_o$ where the transient was the most pronounced.

The oscillator transient response can also be improved by choosing a high gain amplifier with a high degree of linearity and inserting a pair of zener diodes back to back across the amplifier output as shown in figure (27).

![Figure (27)](image)

The resistor $R_9$ is in series with the device and the amplifier $A$. The zener voltage is chosen equal to the peak voltage of the oscillator output in the steady state. The resistor $R_9$ should be a much higher resistance than the dynamic resistance of the zener above the peak voltage $E_1$, and at the same time must be much smaller than the feedback loop load. For any transient within the time response of the zener diode, the zener pair will limit the positive peaks creating components at the harmonic frequencies $3\omega_0, 5\omega_0, 7\omega_0, \ldots$ as well as harmonics and products of $\omega_m$ with $\omega_0$. For small perturbations the amplitude of the fundamental frequency component $\omega_0$ will be reduced by the presence of harmonics in the transient state and the transient time constant and first peak $\delta E_1$ peak will be reduced in the same manner as section V-(a). The important thing is that for an
ideal zener diode pair, the nonlinearity in the steady state will be determined by the nonlinearity of the amplifier.

A double diode combination was constructed from two standard diodes and batteries to provide the same type of limiter characteristic as the zener diodes. The batteries were adjusted to give the proper level of limiting and the oscillator output was observed to contain only a negligible amount of additional distortion in the steady state. The transient response however, was greatly reduced especially with regard to the transient time constant. With the diode limiter adjusted properly, a steady state harmonic distortion of 100db down should be allowable without serious transient disturbances.

A somewhat more subtle use of this method can also be accomplished by adjusting the amplifier to an operating point just below its power point. An amplifier such as the single ended push-pull circuit provides an almost linear characteristic up to the power point and would be suitable for this application. Both of these methods would allow operation with a minimum amount of steady state distortion and still reduce the transient response to an acceptable level for oscillator use.
