Working Paper # 441
August, 1999
Abstract

A new method is devised to calculate the confidence intervals for estimated distances. Using this method, the confidence intervals for estimated actual distances are developed for the \( \ell_p \)-norm and \( \ell_{bp} \)-norm. Our empirical study in the seventeen geographical regions indicates that better confidence intervals for the unknown actual distances are obtained with the \( \ell_{bp} \)-norm than the \( \ell_p \)-norm.
1 Introduction

Distance functions are utilized in several applications such as distribution and transportation planning (Eilon et al., 1971; Westwood, 1977), accuracy validation of actual transportation network distance data (Ginsburgh and Hansen, 1974), response-time models for emergency vehicles (Kolesar et al., 1975), construction of Voronoi Diagrams of a region (Klein, 1988), location-allocation problems (Love et al., 1988), and Geographic Information Systems (Star and Estes, 1990). The software packages Roadnet (Roadnet-Technologies, 1993) and TruckStops2 (MicroAnalytics, 1993) utilize distance predicting functions as a substitute to forming large files of distance data. Distance functions appear within the context of larger models such as facilities location and location-allocation problems (Love et al., 1988). Distance functions are also used in cluster analysis. Murray and Estivill-Castro (1998) examine the effects of the distance function choice on forming cluster regions. Additionally, norm-based distance functions can be employed for generating random problem instances in discrete location or transportation models since they satisfy the triangle inequality by nature.

The Weighted Sum of Order p, denoted by \( \ell_b^p(x) \), can be utilized to estimate distances in a transportation network. The \( \ell_b^p(x) \) distance between any two points \( u = (u_1, u_2) \) and \( v = (v_1, v_2) \) in 2-dimensional Euclidean plane is given by

\[
\ell_b^p(u, v) = |b_1|u_1 - v_1|^p + b_2 |u_2 - v_2|^p, \quad b_1, b_2 > 0, \quad p \geq 1.
\]  

(1)

Love and Morris (1972) introduce the concept of axis rotation in their study on the road network in Milwaukee, Wisconsin. Brimberg, Love and Walker (1995) investigate this concept in detail and conclude that a reference axis rotation chosen to align with the underlying pattern of the transportation network improves the accuracy of distance predictions. Huriot and Perreur (1973) also discuss axis rotation and apply it in a study of the nine largest Swiss cities. Incorporating the axis rotation angle \( \theta \) into the \( \ell_b^p \)-norm we have

\[
\ell_{bp\theta}(u', v') = |b_1|u'_1 - v'_1|^p + b_2 |u'_2 - v'_2|^p
\]  

(2)

1
where

\[ \mathbf{u}' = (u'_1, u'_2), \quad \mathbf{v}' = (v'_1, v'_2), \quad \theta \in [0, \pi/2], \quad \text{and} \]

\[
\begin{pmatrix}
    u'_1 \\
    u'_2 \\
    v'_1 \\
    v'_2
\end{pmatrix} = 
\begin{pmatrix}
    u_1 \\
    u_2 \\
    v_1 \\
    v_2
\end{pmatrix} 
\begin{pmatrix}
    \cos \theta & -\sin \theta \\
    \sin \theta & \cos \theta
\end{pmatrix}.
\]  

(3)

The function \( f_{bp}(x) \) is a norm and is thus a convex function in \( x \) (Üster and Love, 1998). The \( f_{bp} \)-norm is a generalization of the well-known weighted \( \ell_p \)-norm. If for a fixed \( p \), the equality \( b_1^{1/p} = b_2^{1/p} = k \) holds, then one obtains the weighted \( \ell_p \)-norm where \( k \) represents the weight. Furthermore, if \( b_1 = b_2 = 1 \), the rectangular and the Euclidean distances can be obtained from the \( f_{bp} \)-norm by setting \( p = 1 \) and \( p = 2 \), respectively.

With the \( f_{bp} \)-norm one introduces unequal weights or non-symmetric distance irregularities along the axis directions. An empirical work on seventeen geographic regions showed that the \( f_{bp} \)-norm is better than the weighted \( \ell_p \)-norm in terms of the accuracy of distance estimations (Üster and Love, 1998). Particularly in geographical regions with a predominant direction of nonlinearity (e.g. a mountain range), the gain in the accuracy of distance estimations with the \( f_{bp} \)-norm is more pronounced. Furthermore, although the \( f_{bp} \)-norm is a three parameter \((b_1, b_2 \text{ and } p)\) distance function as opposed to a two parameter weighted \( \ell_p \)-norm \((k \text{ and } p)\), the convexity of the goodness-of-fit criterion function in parameters \( b_1 \) and \( b_2 \) provides a close performance in speed for distance fitting algorithms of these norms.

Besides its higher accuracy in predicting distances in a geographical region, the weighted sum of order \( p \) also seems well-suited to some specific applications. Foulds and Hamacher (1990) presents an example in the field of robotics when the movement is restricted to two directions, generated by one motor for each direction. In such an environment and under the assumption that the motors are not allowed to work simultaneously and their constant speeds are equal, the \( \ell_1 \)-norm can effectively be used to determine the minimal time necessary to move from one position in the plane to another. If the assumption of equal speeds of motors is relaxed, then the \( f_{bp} \)-norm with \( p = 1 \), and \( b_1, b_2 \) proportional to the speeds in the corresponding directions, is a suitable function to determine the required minimal travel time. Similar examples are harbor cranes used to move containers around
and plotters used to plot engineering drawings.

Love and Dowling (1985) examine the effect of “doubling back” by fitting the weighted $\ell_p$-norm to a sample of layout patterns which are basically rectangular. They find that while the best value of $p$ stays close to 1 (representing the rectangularity of the layout), the extra travel distance caused by doubling back is captured by the parameter $k$. With the weighted $\ell_p$-norm it is assumed that the effect of doubling back is equal in both horizontal and vertical travel directions. This may not be the case in some types of layouts with dominant directions of travel, such as parallel bays along either horizontal or vertical axis. Suppose that the bays are horizontal and the distance between points $u = (u_1, u_2)$ and $v = (v_1, v_2)$, which are located in different bays, is to be measured. Then, because of the doubling back effect, we expect to travel more than $|u_1 - v_1|$ in the horizontal direction. In such a layout, $b_1$ will be greater than $b_2$ in the $\ell_{bp}$ distance. In other words, $\ell_{bp}$-norm will capture the directional nonlinearity and provide more accurate representation of the underlying pattern than the rectangular distances.

The optimum parameter values of the distance function are determined so that a criterion value is minimized. The criterion also provides the means to measure the accuracy of a distance function. The criterion usually measures the aggregate amount of error generated by a particular distance function with known parameter values. Three criteria have been used to model the parameters of a distance function to a set of data representing a region of interest: Sum of Absolute Deviations ($AD$); Sum of Squared Deviations ($SD$); Sum of Normalized Absolute Deviations ($NAD$). Let $d(a_i, a_j)$ be the predicted distance between points $a_i$ and $a_j$. $A(a_i, a_j)$ is the actual distance between $a_i$ and $a_j$, and $n$ is the number of points in the data set. Then the mathematical expressions for the goodness-of-fit criteria are as follows:

$$AD = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} |d(a_i, a_j) - A(a_i, a_j)|$$

$$SD = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \frac{(d(a_i, a_j) - A(a_i, a_j))^2}{A(a_i, a_j)}$$
The \( AD \) and \( SD \) criteria were introduced by Love and Morris (1972), and the \( NAD \) criterion by Love and Walker (1991). Several applications of the criteria are found in Berens (1988); Berens and Körling (1985); Brimberg, Dowling and Love (1996); Brimberg, Love and Walker (1995); Love and Morris (1972; 1979); Love, Walker and Tiku (1995); and Ward and Wendell (1980; 1985).

Love and Üster (1996) have conducted a detailed study on the statistical comparison of these criteria by using the weighted \( \ell_p \)-norm with axis rotation. The comparisons were carried out using the estimation error distributions for seventeen geographical regions. The authors considered two estimation error related random variables, \( e(a_i, a_j) \) and \( |e(a_i, a_j)|/A(a_i, a_j) \), where \( e(a_i, a_j) = A(a_i, a_j) - k\ell_p(a_i, a_j) \), to statistically compare the criteria in several aspects such as the homoscedasticity and the expected value of \( e(a_i, a_j) \), the homoscedasticity of \( |e(a_i, a_j)|/A(a_i, a_j) \), and the accuracy in predicting long and short distances. The only statistically significant difference found is that, for the \( SD \) criterion, the \( e(a_i, a_j) \) have an expected value of zero without any exceptions in all the regions. Therefore, in this study we will consider the distance estimation errors generated by the \( SD \) criterion. Üster and Love (1998) used the \( SD \) criterion to model the \( \ell_p \) distances in seventeen geographical regions and found that \( \ell_p \)-norm generates lower \( SD \) values and thus better distance estimations. The parameter values of the \( \ell_p \) distances are reported in Table 1.

A confidence interval is calculated by using the estimated distance and it provides the analyst a range in which the actual distance lies in with a predetermined level of expectation. Furthermore, the range provides insight about the accuracy of the estimation and the performance of the distance function employed.

Another application of confidence intervals for road distance is found in the verification of road distance data. Ginsburgh and Hansen (1974) describe an ad hoc range into which the estimated distance must fall to be assumed acceptable. However, the authors do not provide any analytical justification for the range.

\[
NAD = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \frac{|d(a_i, a_j) - A(a_i, a_j)|}{A(a_i, a_j)}
\]
Table 1: Best Parameter Values of the $l_{bp}$-norm

In the literature there are two papers which discuss the statistical properties of errors and confidence intervals for estimated distances. Love, Walker and Tiku (1995) use the weighted $l_p$-norm ($k l_p$) as the distance predicting function and the sum of Normalized Deviations (NAD) as the goodness-of-fit criterion. The authors investigate two types of prediction errors: $e(B_i, a_i)$ and $e(B_i, a_i)/A(B_i, a_i)$, where $e(B_i, a_i) = A(B_i, a_i) - k l_p(a_i, a_j)$, in seventeen geographical regions (nine large geographical regions and eight urban centers). The sample point coordinates and the actual distance data for these seventeen geographical regions are given by Love and Walker (1993). By inspecting the sample Pearson coefficients $\sqrt{b_1}$ (skewness) and $b_2$ (kurtosis) they conclude that both types of error distributions are non-normal. On the other hand, while the scatter of points for the $e(B_i, a_i)$ versus $A(B_i, a_i)$ plots for the regions was contained in a diverging funnel that was symmetric about zero, the scatter of points for the $e(B_i, a_i)/A(B_i, a_i)$ versus $A(B_i, a_i)$ plots was contained within a narrow band which was symmetric about zero. This observation suggested that the $e(B_i, a_i)$ distributions were heteroscedastic but the $e(B_i, a_i)/A(B_i, a_i)$ distributions were homoscedastic. Using
these empirical results it was assumed that $\mu_e = 0$ and $\sigma_e^2 = \sigma^2 A(a_i, a_j)^2$ where $\mu_e$ is the mean of $e(a_i, a_j)$ distribution, and $\sigma_e^2$ and $\sigma^2$ are the variances of $e(a_i, a_j)$ and $e(a_i, a_j)/A(a_i, a_j)$ distributions, respectively. Based on these results, authors devise the following confidence interval for an unknown distance $A(a_i, a_j)$: $c_1 < A(a_i, a_j) < c_2$, where $c_1 = (z_1 s + 1) k e_p(a_i, a_j)$, $c_2 = (z_2 s + 1) k e_p(a_i, a_j)$. The values of $z_1$ and $z_2$ are found by using the sample Pearson coefficients of $e(a_i, a_j)$ distribution from the tables provided by Johnson, Nixon and Amos (1963), and $s^2$ is the sample unbiased estimator of $\sigma^2$.

In another study, Brimberg, Dowling and Love (1994) use the weighted one-two norm as the distance predicting function. The weighted one-two norm is given by the expression

$$h(u, v; \beta_0, \beta_1) = \beta_0 \ell_2(u', v') + \beta_1 \ell_2(u, v'),$$

where $u, v \in \mathbb{R}^2$, $\beta_0, \beta_1 \geq 0$ and $u', v'$ are as defined in (3). Authors apply the weighted one-two norm model by using the regression R-square value as the goodness-of-fit criterion in regions Toronto and Ontario. They also consider two types of errors: $e(a_i, a_j)$ and $e(a_i, a_j)/\ell_2(a_i, a_j)$, where $e(a_i, a_j) = A(a_i, a_j) - h(a_i, a_j; \beta_0, \beta_1)$. Both error distributions are assumed to have a mean zero. To test the normality and homoscedasticity of these distributions authors use the normal probability plots and non-parametric Smirnov test, respectively. It is found that $e(a_i, a_j)$ distributions are non-normal and heteroscedastic in both regions. Additionally, $e(a_i, a_j)/\ell_2(a_i, a_j)$ distributions are heteroscedastic in both regions and from a normal population in Toronto, but from a non-normal population in Ontario. Next, authors analyze the outliers in $e(a_i, a_j)/\ell_2(a_i, a_j)$ distributions and find eight unusual observations for Ontario and five unusual observations for Toronto. After excluding the outliers in Ontario and fitting the distance function again, $e(a_i, a_j)$ distribution stays non-normal and heteroscedastic but $e(a_i, a_j)/\ell_2(a_i, a_j)$ distribution becomes normal and homoscedastic. For Toronto, excluding only two outliers provides normality and homoscedasticity for the $e(a_i, a_j)/\ell_2(a_i, a_j)$ distribution. Based on these results, the confidence intervals are devised by using $e(a_i, a_j)/\ell_2(a_i, a_j)$ variable where outliers are excluded. The confidence interval is $c_1 < A(a_i, a_j) < c_2$, where $c_1 = h(a_i, a_j; \beta_0, \beta_1) - z s \ell_2(a_i, a_j)$, $c_2 = h(a_i, a_j; \beta_0, \beta_1) + z s \ell_2(a_i, a_j)$. The value of $\mp z$ is found from normal probability tables.
by using $e(a_i, a_j)/\ell_2(a_i, a_j)$ distribution.

The rest of this paper is organized as follows: in Section 2, we investigate the statistical properties of the estimation errors generated by the $\ell_{bp}$-norm and the $SD$ criterion in the seventeen geographical regions using the data given by Love and Walker (1993). Then, utilizing these properties we develop an error related random variable which is both homoscedastic and normally distributed at the 5% significance level. Since excluding outliers from a region's sample would weaken the sample's representation of the whole region we also aim to obtain this new random variable without excluding the outliers. In Section 3, we develop confidence intervals for unknown actual distances by using the new random variable. In Section 4 we give some example confidence interval calculations, and compare the the confidence interval calculation method developed in Section 3 with the method provided by Love, Walker and Tiku (1995). In Section 5, we provide a comparison of the distance predicting accuracy of the weighted $\ell_p$-norm and $\ell_{bp}$-norm based on their confidence intervals.

2 Statistical Properties of Estimation Errors

We define the relationship between the fitted distance and the actual distance as

$$A(x_i, x_j) = \ell_{bp}(x_i, x_j) + \varepsilon(x_i, x_j),$$

where $A(x_i, x_j)$ is the actual distance between any two points $x_i$ and $x_j$, $\ell_{bp}(x_i, x_j)$ is the predicted distance, and $\varepsilon(x_i, x_j)$ is the related prediction error term. From a random sample of points taken from a geographical region, the empirical distance predicting function parameters are calculated. A computational procedure for finding the parameters of the $\ell_{bp}$-norm is given by Üster and Love (1998). Substituting these parameters and the point coordinates into the empirical distance predicting function, an estimate of the actual distance, $\ell_{bp}(x_i, x_j)$, is obtained. The error $\varepsilon(x_i, x_j)$ for any pair of points may arise from point coordinate measurements errors, inaccurate instrument calibrations, and road network peculiarities that are not captured by the distance model. Since it is a purely random part of the actual distance $A(x_i, x_j)$, $\varepsilon(x_i, x_j)$ is a continuous random variable. We assume that
the errors for different pairs of points in a region are independent, i.e., the error of \( \ell_{bp}(x_i, x_j) \) about \( A(x_i, x_j) \) is not related to the error of \( \ell_{bp}(x_k, x_l) \) about \( A(x_k, x_l) \) for any four points \( x_i, x_j, x_k, x_l \) in a geographical region.

In order to empirically examine the statistical properties of the \( \epsilon(x_i, x_j) \) distributions for seventeen regions we use the same sample set that we used in fitting the parameters of the \( \ell_{bp} \)-norm. To calculate the predicted distances we use the parameter values given Table 1. For our statistical tests we use the statistical analysis package SPSS® (1997).

To test the normality of the \( \epsilon(x_i, x_j) \) distributions we apply the Kolmogorov-Smirnov test with the Lilliefors correction. The details of this test are given by Lilliefors (1967) and Dallal and Wilkinson (1986). The Lilliefors test is a modification of the Kolmogorov-Smirnov test that examines for normality when means and variances are not known, but must be estimated from the data, and it is based on the largest absolute difference between the observed and the expected cumulative distributions. The p-values of the normality tests for the seventeen regions are reported in Table 2 (Note that the parameter \( p \) of a distance norm and the p-value of a statistical test are different. We use italics "p" to refer to a distance norm's parameter, and "p-value" for a statistical test's significance level). The

Table 2: Normality Tests for \( \epsilon(x_i, x_j) \)

p-values indicate that for most of the cases (10 regions) the \( \epsilon(x_i, x_j) \) distributions are not normally distributed at the 5% significance level. Although the p-values for seven regions are greater than 5%, four of them are not quite convincing. There is significant evidence that \( \epsilon(x_i, x_j) \) is normally distributed only in regions 11, 12 and 15.
Besides the Kolmogorov-Smirnov test, normal probability plots and histograms are examined. The related graphs are given in Appendices A and B. On normal probability plots, a linear relation is expected between the observed cumulative probabilities and the expected cumulative probabilities for a sample distribution to be from a normally distributed population. The histograms are expected to have a symmetric bell-shaped appearance with no violations at the tails. The normal probability plots and histograms also confirm that in general $\varepsilon(x_i, x_j)$ is not normally distributed.

To examine the homoscedasticity (Wesolowsky, 1976) of $\varepsilon(x_i, x_j)$, the sample sets of 105 pairs are divided into three groups (short, medium and long) after they are ordered in their increasing order of predicted distances. In order to clarify what is meant by these three groups, Table 3 is constructed. In Table 3 the means of short, medium and long predicted distance distributions, and also the ratio of medium to short and long to short predicted distance means are listed. The ratios are similar for all regions except Canada.

To test the homoscedasticity of $\varepsilon(x_i, x_j)$ we apply Levene test to three groups of
distributions. A p-value less than 5% indicates that there is at least one pair of groups with a significantly different variance. The Levene test is a powerful test when the data come from continuous, but not necessarily normal, distributions (Kotz and Johnson, 1989). The p-values for the tests are reported in Table 4. The p-values, based on a 5% significance level, suggest that $\varepsilon(x_i, x_j)$ are heteroscedastic in ten of the regions. The homoscedasticity is observed only in the $\varepsilon(x_i, x_j)$ of seven urban centers. In addition to the Levene test we also inspect the scatter plots of errors for our samples. These scatter plots of $\varepsilon(x_i, x_j)$ versus $\ell_{bp}(x_i, x_j)$ are given in Appendix C. We observe that, as expected, as the predicted distance gets larger the amount of prediction error becomes larger. In other words, the scatter plots of $\varepsilon(x_i, x_j)$ versus $\ell_{bp}(x_i, x_j)$ form a diverging funnel.

To test whether the mean of $\varepsilon(x_i, x_j)$, $\mu_\varepsilon$, is zero we employ the Student t-test. Although this test assumes that the data are normally distributed, it is fairly robust to departures from normality. The p-values for the test are given in Table 5. The p-values suggest that $\varepsilon(x_i, x_j)$ has zero mean at the 5% significance level in all seventeen regions. This fact is also observed in the scatter plots where points are evenly scattered about zero.

In general, we can say that $\varepsilon(x_i, x_j)$ is non-normal, heteroscedastic, and its mean is equal to zero at the 5% significance level. In order to develop a confidence interval for an unknown actual distance we need a random variable which is homoscedastic. Therefore we need to use a transformation of $\varepsilon(x_i, x_j)$. For that purpose, we define the following

Table 4: The Levene Tests for $\varepsilon(x_i, x_j)$
transformed random variable:

\[ e_t(x_i, x_j) = \frac{e(x_i, x_j)}{(\ell_{bp}(x_i, x_j))^{1/t}}, \quad t \geq 1, \]

where parameter \( t \) is to be determined for a given transportation network so that the corresponding \( e_t(x_i, x_j) \) is homoscedastic and normally distributed.

Before proceeding with our analysis for finding the best \( t \) value for a transportation network, we will first assume that \( t = 1 \) and investigate if the normalized error \( e_1(x_i, x_j) \) is homoscedastic. This special form of \( e_t(x_i, x_j) \) is very similar to the random variable used by Love, Walker and Tiku (1995). In order to test homoscedasticity we apply the Levene test in the same way that we used it for \( e(x_i, x_j) \). In Table 6 we report the p-values. The scatter plots of \( e_1(x_i, x_j) \) with respect to increasing values of the \( \ell_{bp} \) distance are given in Appendix D. The p-values show that, except in Australia, BC Province, Great Britain, New York State and Paris, the \( e_1(x_i, x_j) \) is heteroscedastic at the 5% significance level. Furthermore, for BC Province and Paris the p-values are very close to 5%. Inspecting the scatter plots in Appendix D we see that the scatter of points form a converging funnel, i.e., in general the percentage error is smaller for relatively long distances and larger for relatively short distances.

We now turn our attention to the determination of the best \( t \) for a given network. For that purpose we generate samples of \( e_t(x_i, x_j) \) for \( t = 1, \ldots, 3 \) with 0.1 increments. In Table 7 we list the ranges of \( t \) in which the \( e_t(x_i, x_j) \) are homoscedastic and normally
Table 6: The Levene Tests for $\varepsilon_1(x_i, x_j)$

distributed. A "✓" represents statistically significant test results at the 5% significance level whereas an "X" represents otherwise. We note that in the United States and London City homoscedasticity could not be obtained for $t \in [1, 3]$. Therefore we exclude the actual distances which correspond to the outliers in the samples of $\varepsilon_1(x_i, x_j)$ for these regions and model the $\ell_p$-norm with the new reduced sample sets. The new samples provided well-behaved distributions for both regions. The number of outliers in the United States case

Table 7: Homoscedasticity and Normality for Ranges of $t$
was five and in the London City case it was nine.

In Table 7 we observe that homoscedasticity is obtained for \( t = 2 \) in all regions, except in the NY City case. However, if \( t = 1 \), then both homoscedasticity and normality are obtained for NY City. Based on our samples we devise the following rule of thumb that can be used in obtaining a transformed random variable for confidence interval calculation purposes: \( e_t(x_i, x_j) \) with \( t = 1 \) is tested for homoscedasticity and normality. Table 7 indicates that both conditions are not very likely to occur in a particular region. If not, then \( e_t(x_i, x_j) \) with \( t = 2 \) is tested for homoscedasticity and normality. Based on our samples it is very likely that a well-behaved distribution will be obtained. In the case that neither \( t = 1 \) nor \( t = 2 \) provides a homoscedastic and normal distribution then other values of \( t \) should be considered. However, if all fails, then the outliers should be excluded and the same checks should be performed with \( t = 1 \) and \( t = 2 \). The \( t \) values determined by using this rule of thumb for seventeen geographical regions are also reported in Table 7. We note that, for purposes of confidence interval calculations, homoscedasticity is more important than normality. In order to obtain a reliable confidence interval the distribution must have a constant variance. Otherwise, one can easily obtain a confidence interval with a lower or higher level of expectation than the predetermined value, say 95%. Therefore, if only a homoscedastic but non-normal \( e_t(x_i, x_j) \) is obtained before excluding the outliers, this distribution can be efficiently used to calculate the confidence interval as shown in the next section. In other words, in order not to weaken the sample’s representation of the whole region, excluding outliers should be seen as a last resort in the course of obtaining a well-behaved error distribution.

### 3 Development of Confidence Intervals

In this section we develop the confidence interval for an estimated distance. For that purpose we use the transformed random variable \( e_t(x_i, x_j) \) where \( t \geq 1 \).

Let \( \mu_{e_t} \) and \( \sigma_{e_t}^2 \) represent the mean and the variance of \( e_t(x_i, x_j) \), herein denoted \( e_t \). Also let \( (\epsilon_{e1}, \epsilon_{e2}) \) be the 100(1 - \( \alpha \))% confidence interval for \( e_t(x_i, x_j) \) where 0 < \( \alpha \) < 1. We
have

\[ \Pr(e_{t1} < \varepsilon_t < e_{t2}) = 1 - \alpha, \quad 0 < \alpha < 1. \]  

(6)

In our development we will assume that the confidence interval is symmetric, i.e., \( \Pr(e_t < e_{t1}) = \Pr(e_t > e_{t2}) = \alpha/2 \). The standardized values of \( e_{t1} \) and \( e_{t2} \) are given by \( z_{t1} \) and \( z_{t2} \) where

\[ z_{t1} = \frac{e_{t1} - \mu_{e_t}}{\sigma_{e_t}} \quad \text{and} \quad z_{t2} = \frac{e_{t2} - \mu_{e_t}}{\sigma_{e_t}}. \]  

(7)

Rearranging (7) and substituting into (6) we have

\[ \Pr(\mu_{e_t} + z_{t1} \sigma_{e_t} < \varepsilon_t < \mu_{e_t} - z_{t2} \sigma_{e_t}) = 1 - \alpha, \]  

(8)

or equivalently

\[ \Pr(z_{t1} \sigma_{e_t} < \varepsilon_t - \mu_{e_t} < z_{t2} \sigma_{e_t}) = 1 - \alpha. \]  

(9)

We assume that \( \mu_{e_t} = 0 \) and \( s_t \) is the sample unbiased estimator of \( \sigma_{e_t} \). Then (9) becomes

\[ \Pr(z_{t1} s_t < \varepsilon_t < z_{t2} s_t) = 1 - \alpha \]

\[ \Pr(z_{t1} s_t < \frac{A(x_i, x_j) - \ell_{bp}(x_i, x_j)}{(\ell_{bp}(x_i, x_j))^{1/t}} < z_{t2} s_t) = 1 - \alpha. \]  

(10)

By rearranging (10) we find the confidence interval for an unknown actual distance between any two points \( x_i \) and \( x_j \) as

\[ \Pr(c_{t1} < A(x_i, x_j) < c_{t2}) = 1 - \alpha, \quad 0 < \alpha < 1. \]  

(11)

where

\[ c_{t1} = \ell_{bp}(x_i, x_j) \left[ 1 + z_{t1} s_t (\ell_{bp}(x_i, x_j))^{(1/t)-1} \right], \]

\[ c_{t2} = \ell_{bp}(x_i, x_j) \left[ 1 + z_{t2} s_t (\ell_{bp}(x_i, x_j))^{(1/t)-1} \right]. \]  

(12)

If \( \varepsilon_t(x_i, x_j) \) is normally distributed, then the standardized values \( z_{t1} \) and \( z_{t2} \) are found in the standard normal distribution table. Since we assume symmetry, the values of \( z_{t1} \) and \( z_{t2} \) are of equal magnitude but opposite sign. For example, if a 95% confidence interval is considered, then the standardized values are \( z_t = \mp 1.96 \). However, if the distribution
is not known, then the standardized values $z_{t1}$ and $z_{t2}$ are found in the tables provided by Johnson, Nixon and Amos (1963). These tables utilize the Pearson coefficients (skewness and kurtosis) of the distribution and list the standardized values for several values of $\alpha/2$. For large samples ($n \geq 100$) the sample Pearson coefficients can be used as unbiased estimates of the population Pearson coefficients (Stuart and Ord, 1987).

4 Some Examples

In this section, we demonstrate the use of (12) by constructing the confidence intervals for six unknown actual distances. We use the regions and the point locations used in constructing example confidence intervals with the weighted $\ell_p$-norm by Love, Walker and Tiku (1995). The regions, point locations (in centimeters), standard deviation of sample $\varepsilon_t(x_i, x_j)$ distributions, and the standardized values $z_{t1}$ and $z_{t2}$ are given in Table 8. For four of the regions the $\varepsilon_t(x_i, x_j)$ are normally distributed (Table 7). Therefore, to construct 95% confidence intervals the values of $z_{t1}$ and $z_{t2}$ are taken as $-1.96$ and $1.96$, respectively. However, for Australia and Toronto, $\varepsilon_t(x_i, x_j)$ is not normally distributed. Thus, to determine the standardized values we have to use the tables provided by Johnson, Nixon and Amos (1963). For Australia the sample Pearson coefficients are $\sqrt{b_1} = 0.4800$ and $b_2 = 4.7524$, and for Toronto they are $\sqrt{b_1} = -0.4086$ and $b_2 = 5.6495$. Using the interpolation technique as described by Johnson, Nixon and Amos we calculate the standardized values given in Table 8. In Table 9 we report the $\ell_p$ distances (in kilometers) and the corresponding 95% confidence intervals.

To compare the confidence interval calculation method developed in the previous section with the Love-Walker-Tiku method, we first calculate the confidence intervals $(c_1, c_2)$ for the $\ell_{bp}$ distances by using the method and the parameters given by Love, Walker and Tiku (1995). Then we compare the range of these confidence intervals with the range of confidence interval calculated by our method. These comparisons are presented in Table 10. We observe that, except in Australia and Brussels, the confidence intervals obtained by the method developed here are smaller than the ones obtained by the Love-Walker-Tiku method. Therefore we next would like to explore this difference.

Let $L$ be a predicted distance, $I$ and $I_t$ be the width of the confidence intervals calculated by the Love-Walker-Tiku method and our method, respectively. Then the expressions for $I$ and $I_t$ are

$$I = L(1 + z_2 s) - L(1 + z_1 s)$$  \hspace{2cm} (13)

$$I_t = L(1 + z_{2t} s_t L^{(1/t)-1}) - L(1 + z_{t1} s_t L^{(1/t)-1})$$  \hspace{2cm} (14)
It can easily be verified that \( I \) and \( I_t \) are increasing functions of \( \mathcal{L} \) and, for \( t > 1 \)

\[
I < I_t \quad \text{for} \quad \mathcal{L} < \mathcal{L}_c
\]

\[
I = I_t \quad \text{for} \quad \mathcal{L} = \mathcal{L}_c
\]

\[
I > I_t \quad \text{for} \quad \mathcal{L} > \mathcal{L}_c
\]

where

\[
\mathcal{L}_c = \left( \frac{\epsilon_t(z_t^2 - z_t^1)}{s(z_2 - z_1)} \right)^{1/(t-1)}
\]  \hspace{1cm} (16)

for \( t = 1 \)

\[
I < I_t \quad \text{for} \quad \mathcal{R} > 1
\]

\[
I = I_t \quad \text{for} \quad \mathcal{R} = 1
\]

\[
I > I_t \quad \text{for} \quad \mathcal{R} < 1
\]

where

\[
\mathcal{R} = \frac{\epsilon_t(z_t^2 - z_t^1)}{s(z_2 - z_1)}
\]  \hspace{1cm} (18)

(15) implies that, for \( t > 1 \), \( I \) and \( I_t \) are equal for a critical \( \mathcal{L} \) value given by (16). This fact is observed in the \( I \) and \( I_t \) graphs which are presented in Figure 1 for five example regions (except Australia for which \( t = 1 \)). For values of \( \mathcal{L} \) greater than \( \mathcal{L}_c \) the range of the confidence interval obtained by the Love-Walker-Tiku method is larger than the one calculated by our method and for values of \( \mathcal{L} \) less than \( \mathcal{L}_c \) the converse holds. Also note that, the difference between the intervals becomes larger, favouring \( I_t \), as the predicted distance increases. For example in Toronto, for the predicted distance of 10.92 kms. the difference between the two intervals is 0.04 (2.92 vs. 2.88 in Table 10). If the predicted distance was 30 kms., the difference would be 3.31 (8.01 vs. 4.70). On the other hand, (17) implies that, for \( t = 1 \), \( I \) and \( I_t \) are equal if \( \mathcal{R} \) is equal to 1. If \( \mathcal{R} \) is less than 1, then the confidence interval calculated by the Love-Walker-Tiku method is larger than the one calculated by our method for any distance \( \mathcal{L} \). The converse holds for values of \( \mathcal{R} \) greater than 1.

The values of \( t \), \( \ell_{bp} \) distances, \( \mathcal{L}_c \) and \( \mathcal{R} \) that we use for comparisons are given in Table 11. Observe that for regions with \( t = 2 \) the predicted distances are longer than their
Figure 1: Example Confidence Interval Comparisons
corresponding critical values $\mathcal{C}_c$, except in Brussels in which case the predicted distance is shorter than $\mathcal{C}_c$. Therefore, as it is already given in Table 10, we obtain smaller confidence intervals for four of the regions, and a larger interval for Brussels. For Australia, where $t = 1$, the $\mathcal{R}$ value is slightly greater than 1, i.e., $I$ and $L_t$ values are very close, $I$ being smaller. This is because for Australia $t$ is equal to 1 and thus $\varepsilon_t(x_i, x_j)$ is indeed quite similar to the transformed random variable used in the Love-Walker-Tiku method. Furthermore, For Australia the weighted $\ell_{bp}$-norm performs similar to the weighted $\ell_p$-norm because of the low directional nonlinearity and high rectangularity in the transportation network as discussed by Üster and Love (1998).

In Table 12 the ranges of predicted distances that represent short, medium and long distance groups for example regions are listed. Notice that, except for Australia, $\mathcal{C}_c$ values are close to the cut-off point between short and medium distance groups. This observation suggests that the confidence intervals calculated by the Love-Walker-Tiku method are generally different than what they should be at the 95% level. They are smaller for relatively short distances and larger for relatively long distances. This is indeed an expected result.

Table 12: Ranges of the Predicted Distance Groups
because, when the $\ell_p$ distances are modelled for these five regions the scatter of points in the $e(a_i, a_j)/A(a_i, a_j)$ versus $A(a_i, a_j)$ plots form a converging funnel (Love and Üster, 1996). In other words, the random variable used in developing confidence intervals is not homoscedastic, but has a higher standard deviation for relatively short distances and a lower standard deviation for relatively long distances. The percentage error generated in predicting long distances is generally lower than the percentage error generated in predicting short distances. We have observed the same phenomenon in predicting distances with the $\ell_{bp}$-norm, i.e., $e_t(x_i, x_j)$ with $t = 1$ is generally heteroscedastic. However, the confidence interval calculation method developed in this paper accounts for this phenomenon and provides confidence intervals at the intended level of expectation.

5 Comparison of Distance Functions

In this section we compare the 95% confidence intervals for the weighted $\ell_p$ and the $\ell_{bp}$ distances modelled using $SD$ as the goodness-of-fit criterion. This, in turn, provides a comparison of accuracy in distance prediction with the weighted $\ell_p$-norm and the $\ell_{bp}$-norm. We use the transformed random variable $e_t(x_i, x_j)$ for that purpose, and adopt the notation $t'$ and $e_t'(x_i, x_j)$ for the weighted $\ell_p$-norm related distributions. To generate the sample $e_t'(x_i, x_j)$ distributions for each region we use the best parameter values of the weighted $\ell_p$-norm, $k$, $p$ and $\theta$, where $p \in (1, 2)$. These empirical parameter values for seventeen geographical regions are computed by Love and Walker (1994) for the $SD$ criterion and are presented here in Table 13.

We first find the best $t'$ values which provide homoscedasticity of $e_t'(x_i, x_j)$. As in the $\ell_{bp}$-norm case we test the homoscedasticity and the normality of sample $e_t'(x_i, x_j)$ distributions for values of $t'$ ranging from 1.0 to 3.0 with increments 0.1. The summary of these test results, including the $t'$ values that are chosen by the rule of thumb devised in Section 2, is given in Table 14. Note that, for $t' \in [1, 3]$, homoscedasticity and normality could not be obtained for the $e_t'(x_i, x_j)$ distributions of the United States and London City. This was also the case for the sample $e_t(x_i, x_j)$ distributions of the same regions. Therefore,

</table>

Table 13: Best Parameter Values for the Weighted $\ell_p$-norm

for comparison purposes, we will not consider these two regions. For the rest of the regions, inspecting $t$ and $t'$ columns in Tables 7 and 14 we see that the chosen values of $t$ and $t'$ are identical, except in regions Canada, Great Britain and Paris. In order to obtain a unified comparison scheme we would like to have equal $t$ and $t'$ values, if possible. Thus, without violating the homoscedasticity requirement of the distributions, we can take $t = 2.1$ for Canada, $t = 2$ for Great Britain, and $t' = 2$ for Paris. The final $t$ and $t'$ values, sample standard deviations, and standardized values for the $\varepsilon_t(x_i, x_j)$ and $\varepsilon_{t'}(x_i, x_j)$ distributions are reported in Table 15. The columns $s_{t_i}$, $z_{t_1}$, and $z_{t_2}$ represent the sample standard deviation and standardized values related to the sample $\varepsilon_{t'}(x_i, x_j)$ distributions. For the error distributions in which normality can not be obtained we calculate the standardized values by interpolation using the sample Pearson coefficients of $\varepsilon_t(x_i, x_j)$ and $\varepsilon_{t'}(x_i, x_j)$, and the biometrika tables of Johnson, Nixon and Amos (1963). We note that the skewness of the sample $\varepsilon_t(x_i, x_j)$ and $\varepsilon_{t'}(x_i, x_j)$ distributions for Tokyo were 2.3707 and 2.4243, respectively. These values are out of the range of skewness values in the biometrika tables where the range is $(0.0, 2.0)$. Thus,
the values of $t$ and $t'$ are taken as 3.3 so that the standardized values can be calculated and both distributions are still homoscedastic.

To compare the two distance functions we will again utilize the range of the confidence intervals. Let $\mathcal{L}$ be any predicted distance as before, and $I_t, I'_t$ be the ranges of the confidence intervals calculated for an $\ell_{bp}$ and a weighted $\ell_p$ distance, respectively. Then using (12) $I_t$ and $I'_t$ for the same predicted distance are given by

$$I_t = \mathcal{L} (1 + z_{12}s_t \mathcal{L}^{(1/t)-1}) - \mathcal{L} (1 + z_{11}s_t \mathcal{L}^{(1/t)-1})$$

$$I'_t = \mathcal{L} (1 + z'_{12}s'_t \mathcal{L}^{(1/t')-1}) - \mathcal{L} (1 + z'_{11}s'_t \mathcal{L}^{(1/t')-1}).$$

It readily follows that the intervals $I_t$ and $I'_t$ are increasing functions of $\mathcal{L}$ and for $t = t'$ we have

$$I_t < I'_t \quad \text{if} \quad T < 1$$

$$I_t = I'_t \quad \text{if} \quad T = 1$$

$$I_t > I'_t \quad \text{if} \quad T > 1$$

Table 14: Homoscedasticity and Normality for Ranges of $t'$
\[ T = \frac{s_t(z_{t2} - z_{t1})}{s_t'(z_{t2}' - z_{t1}')} \]

The values of \( T \) for 15 regions used in the comparisons are calculated and reported in Table 16. Observe that, except in NY State, the \( T \) values are always less than 1, i.e., the confidence intervals calculated for the \( \ell_{bp} \) distances are smaller indicating the superiority of the \( \ell_{bp} \)-norm over the weighted \( \ell_p \)-norm. The proximity of the \( T \) value to 1 determines the level of gained prediction accuracy by using the \( \ell_{bp} \)-norm versus the weighted \( \ell_p \)-norm. The gain in prediction accuracy increases as the \( T \) value becomes smaller. Üster and Love (1998)

</table>

compared the performance of the $\ell_{bp}$-norm and the weighted $\ell_{p}$-norm in predicting distances by using the percent decrease in the $SD$ value of the weighted $\ell_{p}$-norm. These results are summarized here in Table 17. Since the $\ell_{bp}$-norm models the directional nonlinearity in a transportation network explicitly, we observe that the gain increases as the directional nonlinearity increases. In Table 17 we see that a low gain in prediction accuracy (below 7%) is obtained for regions 1, 2, 4, 6, 9, 13, 16 and 17, a moderate gain (10 – 12%) is obtained for regions 3, 7 and 14, and a high gain (above 15%) is obtained for regions 5, 11, 12 and 15. A close inspection of Table 16 reveals that the same groups of regions are formed based on the proximity of $T$ values to unity.

A Normal Probability Plots of $\varepsilon(x_i, x_j)$

- **Australia**
- **Canadian**
- **France**
- **Great Britain**
- **New York State**
B Histograms of $\varepsilon(x_i, x_j)$

- **Australia**
- **British Columbia**
- **Canada**
- **France**
- **Great Britain**
- **New York State**
C Scatter Plots of $\varepsilon(x_i, x_j)$
D Scatter Plots of $\varepsilon_1(x_i, x_j)$

![Scatter plots for Australia, British Columbia, Canada, France, Great Britain, New York State](Image)
Predicted Distance:

- Pennsylvania
- United States
- Brussels
- London City
- London North
- Los Angeles
Predicted Distance

New York City

Paris

Sydney

Toronto

Tokyo
